Sacred lotus (Nelumbo nucifera) regulates temperature in its floral chamber to 32°C to 35°C across ambient temperatures of 8°C to 40°C with heating achieved through high alternative pathway fluxes. In most alternative oxidase (AOX) isoforms, two cysteine residues, Cys1 and Cys2, are highly conserved and play a role in posttranslational regulation of AOX. Further control occurs via interaction of reduced Cys1 with α-keto acids, such as pyruvate. Here, we report on the in vitro regulation of AOX isolated from thermogenic receptacle tissues of sacred lotus. AOX protein was mostly present in the reduced form, and only a small fraction could be oxidized with diamide. Cyanide-resistant respiration in isolated mitochondria was stimulated 4-fold by succinate but not pyruvate or glyoxylate. Insensitivity of the alternative pathway of respiration to pyruvate and the inability of AOX protein to be oxidized by diamide suggested that AOX in these tissues may lack Cys1. Subsequently, we isolated two novel cDNAs for AOX from thermogenic tissues of sacred lotus, designated as NnAOX1a and NnAOX1b. Deduced amino acid sequences of both confirmed that Cys1 had been replaced by serine; however, Cys2 was present. This contrasts with AOXs from thermogenic Aroids, which contain both Cys1 and Cys2. An additional cysteine was present at position 193 in NnAOX1b. The significance of the sequence data for regulation of the AOX protein in thermogenic sacred lotus is discussed and compared with AOXs from other thermogenic and nonthermogenic species.

Thermogenesis in Sacred Lotus

Sacred lotus (Nelumbo nucifera) is a thermogenic plant that regulates the temperature of its floral chamber between 32°C and 35°C for up to 4 d (Seymour and Schultz-Motel, 1996). Heating of plant tissues has been described as an adaptation to attract insect pollinators either by volatilization of scent compounds (Meeuse, 1975) or by providing a heat reward (Seymour et al., 1983), protect floral parts from low temperatures (Knutson, 1974), or provide the optimum temperature for floral development (Ervik and Barfod, 1999; Seymour et al., 2009). In sacred lotus, heat is produced by high rates of alternative pathway respiration (Watling et al., 2006; Grant et al., 2008); however, the mechanisms of heat regulation, which likely occur at a cellular level, remain unclear.

Alternative Oxidase

Alternative pathway respiration is catalyzed by the alternative oxidase protein (AOX), which acts as a terminal oxidase in the electron transport chain but, unlike the energy conserving cytochrome pathway (COX), complexes III and IV are bypassed and energy is released as heat. Traditionally, AOX activity was measured using oxygen consumption of tissue, cells, or isolated mitochondria in the presence or absence of AOX and COX inhibitors. However, this method does not accurately measure activity in vivo but does indicate the capacity of the alternative pathway (Ribas-Carbo et al., 1995; Day et al., 1996). The only method to date to accurately determine AOX activity, that is, flux of electrons through the AOX pathway in vivo, is to use oxygen isotope discrimination techniques (for review, see Robinson et al., 1995). Determining AOX activity in vivo is important because heat production in plants could be due to activity of either the AOX and/or plant uncoupling proteins. Using oxygen fractionation techniques, we have shown that flux through the AOX pathway is responsible for heating in sacred lotus (Watling et al., 2006; Grant et al., 2008). Furthermore, we were unable to detect any uncoupling pro-

tein in these tissues (Grant et al., 2008). AOX protein content within the sacred lotus receptacle increases markedly prior to thermogenesis, but it remains constant during heating (Grant et al., 2008), suggesting that regulation of heating occurs through posttranslational modification of the protein.

Posttranslational Regulation of AOX Protein

The plant AOX is a cyanide-insensitive dimeric protein located in the inner mitochondrial membrane (Day and Wiskich, 1995). The dimer subunits (monomers) can be linked via a noncovalent association (reduced protein) or covalently through the formation of a disulfide bridge (oxidized protein; Umbach and Siedow, 1993). The reduced protein when run on SDS-PAGE has a molecular mass of approximately 30 to 35 kD and the oxidized protein 60 to 71 kD; this holds true for AOX from a number of species, including soybean (Glycine max) roots and cotyledons (Umbach and Siedow, 1993), tobacco (Nicotiana tabacum) leaf (Day and Wiskich, 1995), and the thermogenic spadix of Arum maculatum (Hoefnagel and Wiskich, 1998).

Regulation of AOX has been well studied in nonthermogenic plant species, and two mechanisms have been identified. Most AOX isoforms have two highly conserved Cys residues, Cys$_1$ and Cys$_2$ (defined in Berthold et al., 2000 and Holtzapffel et al., 2003), located near the N-terminal hydrophilic domain of the protein. In these isoforms, Cys$_1$ can either be reduced on both subunits of the AOX dimer, or the Cys$_1$ sulfhydryl groups can be oxidized to form a disulfide bridge (Rhoads et al., 1998). Reduction/oxidation modulation of AOX in vitro can be achieved using the sulfhydryl reductant dithiothreitol (DTT) to reduce the protein or diamide to oxidize the Cys residues. The reduced dimer can be further activated via the interaction of Cys$_2$ with $\alpha$-keto acids, principally pyruvate (Rhoads et al., 1998; see McDonald [2008] for a model of posttranslational regulation of AOX). In addition, Cys$_2$ may also be involved in regulating AOX activity through interaction with the $\alpha$-keto acid glyoxylate (which can also stimulate activity at Cys$_1$; Umbach et al., 2002).

Recently, however, AOX proteins with different regulatory properties have been reported. Naturally occurring AOX proteins without the two regulatory Cys residues have been identified and, along with site-directed mutagenesis studies, used to further elucidate the specific roles of Cys$_1$ and Cys$_2$. The LeAOX1b isoform from tomato (Lycopersicon esculentum) which has a Ser residue at the position of Cys$_2$ and thus does not form disulfide linked dimers, is also activated by succinate rather than pyruvate when expressed in Saccharomyces cerevisiae (Holtzapffel et al., 2003). In Arabidopsis (Arabidopsis thaliana), uncharged or hydrophobic amino acid substitutions of either Cys result in an inactive enzyme, while positively charged substitutions produce an enzyme with higher than wild type basal activity but that is insensitive to pyruvate or succinate (Umbach et al., 2002). Single substitutions at Cys$_1$ or Cys$_2$ have revealed that glyoxylate can activate AOX via both Cys residues, but only one is needed for glyoxylate stimulation (Umbach et al., 2002, 2006). Double substitution mutants were not stimulated by either pyruvate or glyoxylate (Umbach et al., 2006).

Previously, we determined that thermogenesis via the AOX pathway in the sacred lotus receptacle is precisely regulated through changes in AOX flux rather than changes to protein content (Grant et al., 2008). In this study, we investigated the nature of this regulation in mitochondria isolated from heating receptacles. Our aim was to elucidate the reduction/oxidation behavior of the AOX protein and the mechanisms of activation of cyanide-resistant respiration in sacred lotus receptacles to provide insights into the mechanism(s) of heat regulation in this species. We further investigated AOX regulation by determining the amino acid sequence of two novel AOX genes isolated from thermogenic receptacle tissue of sacred lotus.

RESULTS

Activity of Sacred Lotus AOX Is Stimulated by Succinate But Not Pyruvate or Glyoxylate

Residual mitochondrial respiration rates were quite low (<10 nmol O$_2$ min$^{-1}$ mg$^{-1}$ protein). Addition of NADH and KCN stimulated activity to an average of 50 nmol O$_2$ min$^{-1}$ mg$^{-1}$ protein, but this stimulation was not statistically significant. No stimulation was observed with subsequent addition of 5 mM pyruvate (Fig. 1) nor with concentrations of pyruvate up to 20 mM. Addition of succinate, however, produced a 4-fold increase in activity to a mean of 196 ± 20 nmol O$_2$ min$^{-1}$ mg$^{-1}$ protein ($F_{2,20} = 48.70$, $P < 0.0001$; Fig. 1). Activation of respiration by succinate was similar in the presence or absence of malonate, which was used to inhibit complex II. Cyanide-resistant O$_2$ uptake was not stimulated by the addition of glyoxylate, either before or after succinate stimulation (Fig. 1, C–F), and there was no increase in mitochondrial O$_2$ uptake with the possible substrates: citrate, fumarate, oxalate, $\alpha$-ketoglutarate, or malate (data not shown). Manipulation of AOX redox state by addition of the sulfhydryl reductant DTT (Fig. 1B) and diamide had no effect on O$_2$ uptake. Cyanide-resistant oxygen uptake was almost completely inhibited by the AOX inhibitor 6-propyl gallate (Fig. 1, B, D, and F).

The Majority of AOX Protein Does Not Form Disulfide-Linked Dimers in the Presence of Diamide

AOX protein isolated from thermogenic sacred lotus receptacles was predominantly in the reduced form (approximately 32 kD) with only 21% present in the oxidized state (approximately 64 kD; Fig. 2, lane 1). When treated with the reductant DTT (20 mM), almost
all of the protein was present in the reduced state (Fig. 2, lane 2), although a small proportion (12%) remained oxidized. The reduced protein could be partially reoxidized with 10 mM diamide (19%; Fig. 2, lane 3); however, most of the protein was insensitive to diamide even at high concentrations (50–250 mM). In contrast, treatment with the Lys-Lys-specific cross-linker ethylene glycol bis(succinimidylsuccinate) (EGS; 1 mM) caused 76% dimerization of the AOX protein (Fig. 2, lane 4).

Two Novel AOX Isoforms Lacking Cys1 Occur in Thermogenic Sacred Lotus Tissue

Reverse transcription-PCR-based cloning of AOX transcripts was performed with total RNAs from thermogenic receptacles. Because two highly homologous partial fragments were detected during PCR analyses, full-length cDNAs of the corresponding transcripts were isolated and consequently named NnAOX1a and NnAOX1b (DNA data bank of Japan accession nos. AB491175 and AB491176, respectively). The deduced amino acid sequences of the encoded proteins indicate that NnAOX1a and NnAOX1b encode proteins of 39.0 and 39.3 kD, respectively, and 32.5 and 32.6 kD after cleavage of the mitochondrial targeting sequence. Both NnAOX1a and NnAOX1b contain some of the structural features typical of plant AOXs, such as four α-helical bundles and ligands for the two iron atoms of the active center (Moore and Albury, 2008). However, both NnAOX1a and NnAOX1b were found to contain a Ser residue at the site of the highly conserved Cys1 residue, which is necessary for the regulation of the plant AOX through both redox control and α-keto acid stimulation, although the second conserved Cys, Cys2β, was present in both (Fig. 3). Additionally, in the case of NnAOX1b, a Leu residue at position 193 was substituted by Cys (Fig. 3).

NnAOX1a and NnAOX1b Are Similar to AOX Isoforms from Other Dicots

Sequence alignment indicated that NnAOX1a and NnAOX1b are distinct from AOX isoforms reported from other thermogenic species in that they lack Cys1, while Dracunculus vulgaris, Philodendron bipinnatifidum, Sauromatum guttatum, and Symposcarpus reinfolius all contain both Cys1 and Cys2 (Fig. 3). Further analysis indicated that NnAOX1a and NnAOX1b from thermogenic sacred lotus were more similar to AOXs from other dicots than they were to AOXs from other thermogenic plants (Fig. 4; Supplemental Fig. S1).
DISCUSSION

In most plants studied to date, the α-keto acid pyruvate stimulates AOX activity (Day et al., 1994), and the specific site of this regulation is reduced Cys1 (Rhoads et al., 1998). Following pyruvate stimulation, glyoxylate can further increase AOX activity via Cys2 (Umbach et al., 2002) and can also initiate activity at either Cys alone (Umbach et al., 2006). Recent studies on AOX isoforms without the regulatory Cys residues have revealed stimulation by succinate, not pyruvate, when Cys1 is not present (Djajanegara et al., 1999; Holtzapffel et al., 2003), and the glyoxylate effect is absent when both Cys residues are missing (Umbach et al., 2006). Here, we report that AOX from thermogenic tissues of sacred lotus is stimulated by succinate, not pyruvate (Fig. 1A), that there is no glyoxylate effect (Fig. 1, C–F), and that the majority of AOX could not be reversibly reduced and oxidized (Fig. 2). Our results thus suggested that the majority of AOX in these tissues lacked Cys1 and that Cys2 might also be missing. Subsequent sequencing of two cDNAs, NnAOX1a and NnAOX1b, isolated from thermogenic sacred lotus indicated that Cys1 is replaced by Ser but that Cys2 is present in both (Fig. 3). This confirmed our predictions, based on the in vitro studies of isolated mitochondria, that Cys2 was missing from the majority of AOX protein in these tissues. The situation with Cys2 is complicated, however, by the fact that glyoxylate stimulation of AOX containing this residue varies between naturally occurring and site-directed AOX substitutions. For example, similarly to our experiments, glyoxylate failed to stimulate tomato AOX (LeAOX1b) even though it contains Cys2 (Holtzapffel et al., 2003). LeAOX1b was also activated by succinate in a similar fashion to the thermogenic lotus AOX. In contrast, site-directed mutation of both Cys residues in Arabidopsis indicated that only one Cys was needed for glyoxylate stimulation (Umbach et al., 2002, 2006).

In the majority of plants, AOX can be reversibly reduced and oxidized (Umbach and Siedow, 1997). However, when extracted under nonreducing conditions, the sacred lotus receptacle AOX protein was predominantly in the reduced (i.e. nonlinked) state and could not be further oxidized with diamide across a range of concentrations up to 250 mM. This contrasts strongly with AOX proteins from soybean cotyledons and Arabidopsis leaves, where diamide concentrations of <5 mM were sufficient to oxidize AOX (Umbach and Siedow, 1993), while 200 mM diamide was able to oxidize AOX protein from chilled green tomato mitochondria (Holtzapffel et al., 2003). As formation of the oxidized dimer requires the presence of Cys1 (Rhoads et al., 1998; Djajanegara et al., 1999; Umbach et al., 2006), our results are consistent with this regulatory Cys being absent from the majority of AOX found in thermogenic sacred lotus. This results in an AOX that is permanently in the reduced state and ready for further activation by succinate. Thus, fine control of activity during heating may be modulated by succinate levels. Similarly, naturally occurring and mutated AOX proteins with Ser substitutions at Cys1 lack the ability to form oxidized dimers and, like the sacred lotus receptacle AOX, are poised for activation (Ito et al., 1997; Umbach et al., 2002; Holtzapffel et al., 2003; Umbach et al., 2006).

In contrast to the results with diamide, AOX from the sacred lotus receptacle was able to form dimers when exposed to the Lys-Lys cross-linker EGS. Monomeric AOX proteins such as those found in fungi (e.g. Neurospora crassa and Pichia stipitis) do not form dimers in the presence of EGS or diamide (Umbach and Siedow, 2000). Thus, while most of the thermogenic sacred lotus AOX protein is able to be covalently bound, only a small fraction (approximately 20%) can form disulfide bonds in the presence of diamide (Fig. 2). This suggests that there may be an additional isoform that unlike NnAOX1a and NnAOX1b contains Cys1. Alternatively, there is the possibility that the additional Cys at position 193 in NnAOX1b may be involved in disulfide bridge formation, although this
Cys may not be close enough to Cys₂ in the tertiary or quaternary structure of the protein to form disulfide bonds (Gilbert, 1990). Interestingly, a further isoform may be present in thermogenic sacred lotus, as we detected a small band around 60 kD that could not be reduced in the presence of DTT (Fig. 2, lane 2). This band represented around 12% of the total AOX protein present in our samples. Multiple AOX isoforms in the same tissue have been reported in a number of different species, including thermogenic *S. guttatum* (Rhoads and McIntosh, 1992). It is possible that these different isoforms could form heterodimers.

**Figure 3.** Deduced amino acid sequences of NnAOX1a and NnAOX1b aligned with those of previously reported AOXs expressed in thermogenic tissues. Bold characters highlight residues conserved across all of the AOX sequences in the alignment. The putative structural features are indicated as follows: asterisks for two highly conserved Cys residues, termed Cys₁ and Cys₂ (Berthold et al., 2000), double underline for ligands to iron atoms of the catalytic center, and gray bars for four α-helices. Abbreviations and data sources are as follows: DvAOX, *D. vulgaris* AOX (BAD51465); PbAOX, *P. bipinnatifidum* AOX (BAD51467); SgAOX, *S. guttatum* AOX (P22185); SrAOX, *S. renifolius* AOX (BAD38866).
heterodimers have been proposed to occur in soybean (Finnegan et al., 1997), while in tomato it was suggested that heterodimeric associations between LeAOX1a and LeAOX1b could explain why full oxidation of tomato AOX dimers did not occur (Holtzapffel et al., 2003). Whether AOX heterodimers occur in thermo-reginic sacred lotus and whether they have different catalytic properties from homodimers has yet to be investigated. Crichton et al. (2005) suggested that changes to amino acids other than the regulatory Cys, and Cys2 may influence AOX activity in thermogenic species. This suggestion is based on a constitutively active SgAOX, with both conserved Cys residues, which when expressed in yeast was insensitive to both pyruvate and succinate. However, the absence of Cys2 in both NnAOX1a and NnAOX1b, and the fact that succinate was required for full alternative pathway activity in mitochondria isolated from thermogenic sacred lotus, make it unlikely that these isoforms are regulated in a similar way to that hypothesized for S. guttatum (Crichton et al., 2005). Furthermore, AOX proteins that have been modified by amino acid substitutions or expressed in bacteria or yeasts may not reflect in vivo behavior; thus, comparisons with naturally occurring isoforms need to be approached with caution. Unlike previous studies, the AOX lacking Cys1 in sacred lotus is a naturally occurring isoform expressed in plant mitochondria.

**Figure 4.** Unrooted dendrogram of a range of plant AOX proteins showing three distinct groups of AOX proteins: monocot AOX1, dicot AOX1, and dicot AOX2. more closely aligned with AOXs from other dicots than with those from other thermogenic plants, all of which are monocots (Fig. 4). Based on our phylogenetic analysis, the two deduced sacred lotus AOX sequences were more similar to GhAOX1 from cotton (*Gossypium hirsutum*) than to any other AOX. It was also interesting that the only dicot AOX that fell within the same group as the thermogenic monocots was LeAOX1b from tomato. These results suggest that there is no specific AOX sequence associated with thermogenic activity in plants, rather it may be the amount of AOX synthesized that allows these plants to generate heat. This is further supported by the fact that there appear to be only a few mechanisms of post-translational regulation for AOX proteins from a wide variety of species and that the same mechanism may be shared by both nonthermogenic and thermogenic plants. For example, succinate activation of AOXs in which Cys1 has been replaced by Ser is found in both thermogenic sacred lotus and nonthermogenic tomato (Holtzapfel et al., 2003). Similarly, pyruvate activation via reduced Cys1 occurs in both thermogenic and nonthermogenic plants (Day et al., 1994; Onda et al., 2007). Modulation of AOX activity by either succinate or pyruvate could be important for those plants that thermoregulate, such as sacred lotus (Seymour and Schultze-Motel, 1996), *S. renifolius* (Knutson, 1974), and *P. bipinnatifidum* (Nagy et al., 1972). In contrast, *S. guttatum*, the only thermogenic plant in which a constitutively active AOX has been found, does not thermoregulate. Rather, this species has a single burst of heat production that lasts only a few hours (Meuse, 1966).

Our observation that succinate stimulation of AOX occurs in thermogenic sacred lotus mitochondria even in the presence of malonate (a succinate dehydrogenase inhibitor) suggests a possible nonmetabolic interaction of succinate with the AOX protein. As succinate is a common TCA cycle intermediate, it is possible that the isoform of the protein present. The organic acids pyruvate or succinate, depending on which isoform of the protein is present.

**CONCLUSION**

Through a combination of biochemical and molecular techniques, we have investigated the regulation of AOX activity in thermogenic tissues of sacred lotus. This has enabled us to expand our understanding of how heating may be regulated in this and other thermoregulating species. The major isoforms of AOX found in lotus, NnAOX1a and NnAOX1b, lack Cys1 and could therefore not form disulfide linked dimers. The lack of Cys1 also explains the pyruvate insensitivity of alternative pathway respiration in thermogenic lotus and also suggests that Cys-193, present in NnAOX1b, does not substitute for pyruvate activation via Cys1. Our sequence data indicated that AOXs from thermogenic plants do not form a functional grouping and that heating in these plants may thus be a function of the amount of AOX protein present rather than the structure of the protein. Fine control of AOX activity in thermoregulating species is yet to be elucidated but may involve modulation by the organic acids pyruvate or succinate, depending on which isoform of the protein is present.

**MATERIALS AND METHODS**

**Plant Material**

Lotus flowers (*Nelumbo nucifera*) were collected from an outdoor pond in the Adelaide Botanic Gardens, South Australia, in January and February 2007 to 2009. Flowers for mitochondrial measurements were collected early during the thermoregulatory period classified as stage 1 by Grant et al. (2008). Stage 2 flowers were used for isolation of total RNA.

**Isolation of Mitochondria**

Washed mitochondria were isolated from approximately 50 g of fresh sacred lotus receptacle tissue according to Day et al. (1985) with minor modifications (Grant et al., 2008). The mitochondria were purified using a three-step Percoll gradient (30 mL) made of equal amounts of 50% (v/v), 35% (v/v), and 20% (v/v) Percoll in a Suc wash buffer (250 mM Suc, 10 mM HEPES-KOH, pH 7.2, and 0.2% [w/v] fatty acid-free bovine serum albumin [BSA]). The gradients were centrifuged at 20,000g for 1 h at 4°C, and purified mitochondria were collected from the 20% to 35% interface. Mitochondria were then washed (0.4 M mannitol, 10 mM MOPS-KOH, pH 7.2, and 0.1% [w/v] fatty acid-free BSA) twice by centrifugation at 10,000g and the final pellet resuspended in 1 mL wash buffer. Mitochondrial protein was determined according to the method of Bradford (1976).

**Treatment of Mitochondria with Diamide and DTT**

Percoll purified mitochondria were left untreated or treated with either DTT, diamide, or EGS to final concentrations of 20, 10, and 5 mM, respectively. Higher concentrations of EGS completely cross-linked the AOX protein; however, the AOX signal was greatly reduced. A high dimethyl sulfoxide (DMSO)/protein ratio may have had a detrimental effect on the protein; therefore, lower concentrations of EGS were used. Following the addition of DTT, mitochondria were incubated on ice for 30 min. Mitochondria treated with EGS or diamide (30 min at room temperature) were incubated with DTT first, to ensure the AOX protein was in the reduced form, and then washed before addition of the aforementioned reagents. Reactions were quenched by adding excess Tris-HCl (1 M, pH 7.4). Stock solutions of diamide and EGS were prepared in DMSO. The DTT was prepared in purified water; however, DMSO was added to both DTT-treated and untreated mitochondria at the same final concentration as in the diamide treatment as a control. All solutions were prepared fresh on the day of use.

**SDS-PAGE and Immunoblotting**

Mitochondrial protein samples were separated by nonreducing SDS-PAGE gels and immunoblotted as previously described (Grant et al., 2008). Anti-
bodies raised against **Sauromatum guttatum** AOX (Elthon et al., 1989) were used to detect the AOX protein. The proteins were visualized using SuperSignal west fermo maximum sensitivity substrate (Pierce). All buffers were reductant free.

### Mitochondrial Respiration Measurements

Oxygen uptake by purified mitochondria was measured at 25°C using a Clark-type oxygen electrode in 1.8 ml of reaction medium (0.2 m Suc, 10 mM KC1, 1 mM MgCl2, 5 mM KH2PO4, 20 mM MOPS/KOH, pH 7.2, and 0.1% [w/v] fatty acid-free BSA). The O2 concentration in air-saturated buffer at 25°C was estimated at 250 μM. In the experiment, mitochondrial O2 uptake was initiated with 2 mM NADH and 20 mM succinate (final cuvette concentration). Approximately 100 μg of mitochondrial protein was used in each assay. KCN at a final concentration of 1 mM was used to inhibit the COX pathway, and 100 μM n-propyl gallate was used to inhibit the AOX pathway. A steady state of O2 uptake was reached before transition of subsequent constituents. Depending on the experiment, the following were added to the reaction mix (shown as final cuvette concentration): 20 mM pyruvate, 5 mM glycolysate, 10 mM citrate, 10 mM fumarate, 10 mM α-ketoglutarate, 10 mM malate, 5 mM DTT, and 5 mM diadme. To account for the effect of residual pyruvate, lactate dehydrogenase (5 units/mL) was added to the reaction medium to scavenge residual pyruvate. Malonate (1–10 mM) was used to determine whether succinate was acting as a substrate for succinate dehydrogenase (complex II) or as an activator of AOX. Initial experiments showed no evidence of state 3 to state 4 transition following the addition of ADP, and the succinate-stimulated O2 uptake was not inhibited by KCN, suggesting that the bulk of respiration was occurring via the AOX pathway.

### Isolation and Sequencing of the Full-Length NnAOX1a and NnAOX1b

For the isolation of transcripts encoding AOX proteins by reverse transcription-PCR, total RNA was first extracted from thermogenic receptacles using Fruit-mate (Takara Bio) and the FastPure RNA kit (Takara Bio). Quality of the isolated RNAs was checked using the FastClcl System (Lonza). First-strand cDNAs were generated with PrimeScript first-strand cDNA synthesis kit (TaKaRa Bio) using oligo(dT) primer. By aligning conserved cDNA sequences of AOX transcripts across several thermogenic plants, *Dracunculus vulgaris* AOX (Ito and Seymour, 2005), *Philodendron bipinnatifidum* AOX (Ito and Seymour, 2005), and *S. guttatum* AOX (Rhoads and McIntosh, 1991), primers were designed to amplify partial fragments: NnAOX1 (5'-ACA-GCGGCCGCGGATCAAGGCCCTCCTC-3') and NnAOX1b (5'-TCCGGGCGGGTGGATCAAGGCCCTCCT-3'). The obtained fragments were cloned into pCR 2.1 with TA cloning kit (Invitrogen) and then sequenced.

### Statistical Analysis

Changes in mitochondrial activity with respect to different substrates were compared using one-way ANOVA (JMP 5.1, SAS Institute). Tukey’s honestly significant difference post hoc tests were used to identify significantly different means. Data sets were tested for normality and homogeneity of variances using Shapiro-Wilk W and Bartlett’s tests, respectively. Significant differences between means were calculated at P = 0.05.

Sequence data from this article can be found in the GenBank/EMBL data libraries under accession numbers AB491175 (NnAOX1a) and AB491176 (NnAOX1b).

### Supplemental Data

The following materials are available in the online version of this article.

**Supplemental Figure S1.** Sequence alignment of NnAOX1a, NnAOX1b, and AOX1 proteins from other dicot species.

### ACKNOWLEDGMENTS

We thank the Adelaide Botanical Gardens for access to their lotus pond, Laura Howie for technical assistance, Associate Professor Kathleen Soole, and Professor James Whelan for the kind donation of AOX antibodies. We also thank two anonymous reviewers for their constructive and insightful comments.

Received April 6, 2009; accepted April 13, 2009; published April 22, 2009.
