In higher plants, the most abundant sterol derivatives are steryl glycosides (SGs) and acyl SGs. Arabidopsis (Arabidopsis thaliana) contains two genes, UGT80A2 and UGT80B1, that encode UDP-Glc:sterol glucosyltransferases, enzymes that catalyze the synthesis of SGs. Lines having mutations in UGT80A2, UGT80B1, or both UGT80A2 and UGT80B1 were identified and characterized. The ugt80A2 lines were viable and exhibited relatively minor effects on plant growth. Conversely, ugt80B1 mutants displayed an array of phenotypes that were pronounced in the embryo and seed. Most notable was the finding that ugt80B1 was allelic to transparent testa15 and displayed a transparent testa phenotype and a reduction in seed size. In addition to the role of UGT80B1 in the deposition of flavanoids, a loss of suberization of the seed was apparent in ugt80B1 by the lack of autofluorescence at the hilum region. Moreover, in ugt80B1, scanning and transmission electron microscopy reveals that the outer integument of the seed coat lost the electron-dense cuticle layer at its surface and displayed altered cell morphology. Gas chromatography coupled with mass spectrometry of lipid polyester monomers confirmed a drastic decrease in aliphatic suberin and cutin-like polymers that was associated with an inability to limit tetrazolium salt uptake. The findings suggest a membrane function for SGs and acyl SGs in trafficking of lipid polyester precursors. An ancillary observation was that cellulose biosynthesis was unaffected in the double mutant, inconsistent with a predicted role for SGs in priming cellulose synthesis.

Steryl glycosides (SGs) and acyl SGs (ASGs) are abundant constituents of the membranes of higher plants (Frasc and Grunwald, 1976; Warnecke and Heinz, 1994; Warnecke et al., 1997, 1999). SGs are synthesized by membrane-bound UDP-Glc:sterol glucosyltransferase (Hartmann-Bouillon and Benveniste, 1978; Ury et al., 1989; Warnecke et al., 1997), which catalyzes the glycosylation of the 3\(\beta\)-hydroxy group of sterols to produce a 3\(\beta\)-D-glycoside. UGT80A2 has been found in the plasma membrane, Golgi vesicles, the endoplasmic reticulum membrane, and occasionally the tonoplast (Hartmann-Bouillon and Benveniste, 1978; Yoshida and Uemura, 1986; Ullmann et al., 1987, Warnecke et al., 1997). It has also been reported that a UDP-Glc-dependent glucosylceramide synthase from cotton (Gossypium hirsutum) is capable of synthesizing SG in plants (Hillig et al., 2003). All plant sterols can be glycosylated, given that sterol substrates are pathway end products (\(\Delta^3\)-sterols in Arabidopsis [Arabidopsis thaliana]) and not intermediates. The most commonly observed glycoside is Glc (Warnecke et al., 1997) but Xyl (Iribarren and Pomilio, 1985), Gal, and Man have been observed (Grunwald, 1978). Although rare in...
occurrence, SGs with di-, tri-, and tetraglucoside residues have also been reported (Kojima et al., 1989). SGs can be acylated, polyhydroxylated, or sulfated, but ASGs with fatty acids esterified to the primary alcohol group of the carbohydrate unit are the most common modifications (Lepage, 1964).

SGs have been found as abundant membrane components in many species of plants, mosses, bacteria, fungi, and in some species of animals (Esders and Light, 1972; Mayberry and Smith, 1983; Murakami-Murofushi et al., 1987; Haque et al., 1996), yet relatively little is known about their biological functions. Because of the importance of sterols in membrane fluidity and permeability (Warnecke and Heinz, 1994; Warnecke et al., 1999; Schaller, 2003) and the phospholipid dependence of UDP-Glc:sterol glucosyltransferase (Bouvier-Nave et al., 1984), it has been postulated that SGs may have a role in adaptation to temperature stress (Palta et al., 1993). A difference in the proportion of glycosylated versus acylated sterols were reported in two different solanaceous species under the same cold acclimation experiment (Palta et al., 1993). In one species an increase in SG was correlated with a decrease in ASG. In contrast, the other species displayed no change in SG and ASG levels with cold acclimation conditioning. Hence, evidence for a role in temperature adaptation is lacking.

Understanding the processes involved in SG production has additional human importance because SGs are highly bioactive food components and laboratory mice fed SGs faithfully lead to either amyotrophic lateral sclerosis or parkinsonism pathologies (Ly et al., 2007). Similarly, consumption of seeds of cycad palm (Cycas micronesica), containing high SG levels, has been linked to an unusual human neurological disorder, amyotrophic lateral sclerosis-parkinsonism dementia complex, in studies of the people of Guam (Cruz-Aguado and Shaw, 2009). However, SG is a dominant moiety of all plant membranes and some of the most widely consumed plant products in the United States such as soybeans (Glycine max) have concentrations well within the dose range obtained by people of Guam (Cruz-Aguado and Shaw, 2009). How- ever, SG is a dominant moiety of all plant membranes and some of the most widely consumed plant products in the United States such as soybeans (Glycine max) have concentrations well within the dose range obtained by consumption of cycad seeds. Cholesterol glycoside is the SG most commonly identified in animal membranes and is exemplified by cases in snake epidermis cells (Abraham et al., 1987) and human fibroblast cells under heat shock (Kunimoto et al., 2000). Regarding a role for SGs in the membrane, in comparison to normal sterols, SG and ASG exchange more slowly between the monolayer halves of a bilayer, which could serve to regulate free sterol (FS) content and its distribution (Üllmann et al., 1987; Warnecke et al., 1999).

A study of cellulose synthesis in herbicide-treated cotton fibers found that sitosterol β-glucoside (SSG) copurified with cellulose fragments (Peng et al., 2002), leading to speculation that SGs act as a primer for cellulose biosynthesis in higher plants (Peng et al., 2002). In support of the hypothesis, SSG biosynthesis was reported to be pharmacologically inhibited by the known cellulose biosynthesis inhibitor 2,6-dichlorobenzonitrile (DCB; Peng et al., 2002). However, in subsequent studies, DCB inhibition of cellulose synthesis was not reversed by the exogenous addition of SSG, and the effects of DCB on cellulose synthesis were so rapid that the turnover of SGs would need to be very fast to account for the effects of DCB on cellulose synthesis (DeBolt et al., 2007). Schrick et al. (2004) reported that sterol biosynthesis mutants fackel, hydra1, and sterol methyltransferase1/cephalopod have reduced levels of cellulose but a specific effect on SGs was not established. Hence, a role for SGs in plant growth and development remains speculative.

Here we describe a genetic analysis of the biological roles of two isoforms of UDP-Glc:sterol glucosyltransferase, UGT80A2 and USGT80B1, that participate in the synthesis of SG in Arabidopsis. UDP-Glc-dependent glucosylceramide synthase may also be capable of synthesizing SG in plants (Hillig et al., 2003), but no analysis was performed herein. We show that mutations in one of these genes, UGT80B1, results in a lack of flavanoid accumulation in the seed coat and that it corresponds to transparent testa15 (t15). Analysis of ugt80A2, ugt80B1, and a double mutant suggests that glycosylation of sterols by the UGT80A2 and UGT80B1 enzymes had no measurable consequence on cellulose levels in Arabidopsis seed, siliques, flowers, stems, trichomes, and leaves. Rather, we demonstrate that mutation of UGT80B1 principally alters embryonic development and seed suberin accumulation and cutin formation in the seed coat, leading to abnormal permeability and tetrazolium salt uptake.

RESULTS

Isolation of T-DNA Mutations in the Genes Encoding UDP-Glc:Sterol Glucosyltransferase

Warnecke et al. (1999) previously reported the isolation of a cDNA coding for UDP-Glc:sterol glucosyltransferase from Arabidopsis. The gene they described, At3g07020, which we designate here as UGT80A2, encodes a 637-amino acid protein comprised of 14 exons and 13 introns. The completion of the Arabidopsis genome sequence revealed the existence of a second unlinked gene, At1g36230, encoding a 615-amino acid protein and corresponding to a genomic region encompassing 14 exons and 13 introns, as well as a predicted intron in the 3′ untranslated region. The predicted protein product that we designate as UGT80B1 exhibits strong sequence identity to UGT80A2 (61.5% and 51.2% amino acid similarity and identity, respectively).

T-DNA insertion alleles for both UGT80A2 and UGT80B1 were identified by screening the University of Wisconsin T-DNA collection (Sussman et al., 2000). Homozygous lines carrying T-DNA mutations in UGT80A2 and UGT80B1 were confirmed by PCR (Supplemental Fig. S1). A double mutant homozygous for both the ugt80 (B1 and A2) mutations was obtained by crossing ugt80A2 and ugt80B1 homozygous plants,
followed by PCR screening of the F2 population for the double homozygote. The double mutant was found to be viable and was designated \textit{ugt80A2,B1}.

### Sterol and Sterol-Derivative Analysis Reveals Reduced Levels of SG and ASG and Increased FSs in the \textit{ugt80A2,B1} Mutant

FSs, steryl esters (SEs), SG, and ASG were isolated from leaf tissue of wild-type, \textit{ugt80A2}, and \textit{ugt80B1} mutants, and the \textit{ugt80A2,B1} double mutant. The wild-type tissues contained FS, SG, and ASG, at levels that are similar to those previously described (Patterson et al., 1993). There was no difference in FS + SE content between wild type and \textit{ugt80A2,B1} in leaf or stem tissue (Fig. 1A). However, in inflorescence + silique tissue FS + SE content was 26% higher in \textit{ugt80A2,B1} relative to wild type (Fig. 1A). SG + ASG content decreased 5-, 21-, and 22-fold in leaf, stem, and siliques + inflorescence tissue, respectively (Fig. 1B). Sterol derivatives that were SG + ASG were significantly reduced in \textit{ugt80A2} and \textit{ugt80B1} mutants (Supplemental Table S1). The ratio of SG + ASG:FS (%) for rosette leaf tissue and ASG:SE (%) for stem and inflorescence tissue both showed additive alteration in the sterol profile between the single and double mutant (Supplemental Table S1). Thus, both \textit{UGT80A2} and \textit{UGT80B1} are required for the normal production of SG and ASG, and their gene products appear to function in a partially redundant manner in catalyzing the glycosylation of 24-alkyl-$\Delta^5$-sterols in Arabidopsis.

### SG Mutant \textit{ugt80A2,B1} Exhibits a Slow Growth Phenotype and Elongation Defects in Embryogenesis

The mature \textit{ugt80A2}, \textit{ugt80B1}, and double-mutant plants were viable and fully fertile. At 22°C the growth habit of the mature plants showed no substantial radial swelling or dwarfing as was expected for a cellulose-deficient mutant. Because of evidence suggesting that SG may be important in stress responses in fungi (Warnecke et al., 1999), slime molds (Murakami-Murofushi et al., 1987), and plants (Patterson et al., 1993), we grew the mutants at the seedling stage at a range of temperatures from 10°C to 22°C. The results indicated significantly lower seedling growth rates in the double mutant compared to wild-type, \textit{ugt80A2}, and \textit{ugt80B1} single mutants at all 22°C, 15°C, and 10°C temperatures (Supplemental Fig. S2). We also explored the ability of the plants to acclimate to cold by measuring ion leakage and survival rates after 1 week acclimation at 4°C but observed no significant difference between any of the lines and wild type (Supplemental Fig. S3). Mutant and wild-type parental plants grown on soil at 4°C for 5 months in 24-h light also displayed no differences in height or growth habit of the plants (data not shown).

Since double mutants displayed a slow growth phenotype during postembryonic stages, we asked whether growth during embryogenesis was also affected. Embryonic stages of development were compared between the wild type and double mutant (Fig. 2). Although the early stages of double-mutant development, from globular to young heart stages, displayed morphologies that were similar to wild type, the late heart, torpedo, bent-cotyledon, and mature embryo stages exhibited abnormally stunted morphologies, indicating a defect in cell elongation (Fig. 2). Elongation of the cotyledon primordia, developing hypocotyl, and embryonic root were affected.

### Cellulose and Cell Wall Sugar Levels Are Not Significantly Altered in SG Mutants

The cellulose priming model (Peng et al., 2002) predicts that a deficiency in SG may alter cellulose synthesis. To test this hypothesis we measured the relative amounts of crystalline Glc derived from cellulose in flowers, siliques, leaves, trichomes, and stems...
of the double mutant. The results of these measurements indicated no significant difference in the amount of cellulose in the mutants in comparison with wild-type plants in any of our experiments (Fig. 3A). Cellulose measurements were performed on leaf trichomes using birefringence and the results also failed to uncover a deficiency in cellulose content in the double mutant as did Fourier transform infrared analysis (data not shown). Neutral sugar analysis showed some minor differences in the sugar profile of the cell wall (Fig. 3B). Specifically, in the ugt80B1 mutant Xyl, Man, and Glc content appeared greater than that of the wild-type plant and the ugt80A2 had slightly greater Glc levels than wild type.

Promoter::GUS Fusions Indicate Distinct But Partially Overlapping Relative Gene Expression Patterns for UGT80A2 and UGT80B1

To investigate UGT80A2 and UGT80B1 expression in more detail, we constructed transgenic plants in which the GUS reporter gene was placed under the control of the approximately 2-kb promoter regions upstream of the UGT80A2 and UGT80B1 genes. Relative gene expression of proUGT80A2::GUS was observed in a patchy distribution in cauline leaf epidermal cells, stomata, pollen, around the base of siliques and in the stamen (Supplemental Fig. S4). Relative gene expression of proUGT80B1::GUS was primarily observed in leaves, seedlings, around the apical tip of cotyledons, and developing seeds (Supplemental Fig. S5). Characterization of the GUS staining pattern in embryos revealed that expression was strongest around the apical tip of the cotyledons and at the root apex. Strong GUS expression was also apparent around the seed coat epidermal cell boundaries and in the central columella, but not in the trough (Supplemental Fig. S5). Taken together the results indicate that UGT80A2 and UGT80B1 mRNAs are found in distinct expression domains within the plant. UGT80B1 was uniquely expressed in the seed coat and in the cotyledons of the embryo, consistent with its mutant phenotype related to these tissues. The promoter fusion expression results for both genes are largely consistent with expression analysis performed using available microarray data for Arabidopsis.
Mutations in *UGT80A2* and *USG80B1* Genes Result in Reduced Seed Size, Transparent Testa, and Salt Uptake Phenotypes

Visual inspection revealed a lightened seed coat hue in *ugt80B1* and in the double mutant as well as a dramatic reduction in seed size compared to wild type (Fig. 4A; Supplemental Fig. S6). The light-colored testa phenotype in the *UGT80B1* mutant was consistent with being a transparent testa mutant and this was confirmed by allelism tests to *tt15* (data not shown; Focks et al., 1999). The color of seed from *ugt80A2* mutants did not appear lightened to the same degree as *ugt80B1*, however *ugt80A2* seeds displayed a measurable reduction in size (Fig. 4A; Supplemental Fig. S6).

A series of histochemical and microscopy analyses were performed to deduce possible reasons for the increased permeability of the *ugt80B1* mutant. When seeds were incubated in a solution of tetrazolium salts, *ugt80B1* and the double-mutant seed were found to be highly sensitive to salt uptake (Fig. 4B). Wild-type and *ugt80A2* seeds absorbed small amount of salt at the hilum region, but *ugt80B1* seeds were unable to limit uptake and the entire embryo became stained with formazan dye (a tetrazolium reduction product; Fig. 4B). The salt-uptake phenotype of *ugt80B1* mutants was rescued by complementation with a *p35S::UGT80B1* construct (Fig. 4B). Additional salt-uptake experiments were performed during the development of the embryo within the seed. Wild-type seeds restricted salt uptake during the maturation stages, whereas double mutants never developed the ability to restrict salt from penetrating the seed coat (data not shown).

Pigmentation of the seed coat was determined by the deposition of flavanoids using 4-(dimethylamino)cinnamaldehyde (DMACA) reagent. Consistent with the transparent testa phenotype, the most drastic reduction in DMACA staining was in *ugt80B1* and in the double mutant (Fig. 4C). The DMACA staining phenotype of *ugt80B1* mutants was also rescued by complementation with a *p35S::UGT80B1* construct (Fig. 4C).

Flavanol and Starch Analysis in the Seedling Reveals Altered Cotyledon Morphology and Hydathode Composition in *ugt80B1* Mutants

Seedlings were grown in the dark for 3 d and then stained with diphenylboric acid 2-aminoethyl ester (DPBA) to reveal sinapate derivatives. In comparison to wild type, the *ugt80B1* mutant displayed a striking increase in sinapate derivatives (blue color) localized specifically at the apical hydathode in the cotyledon (Supplemental Fig. S7A). The double mutant did not show a substantial change from the *ugt80B1* single mutant in the DPBA staining pattern at the hydathode.

![Figure 3. Cellulose and cell wall analysis.](https://3.met.genevestigator.com/)

![Figure 4. Transparent testa phenotype of *ugt80B1* and *ugt80A2,B1* mutants.](https://3.met.genevestigator.com/)
After 2 d of dark growth, wild-type seedlings exhibited blue-colored sinapate derivatives that were only localized at the hydathode region whereas in ugt80B1 and the double mutant, almost half the cotyledon showed sinapate derivatives. Thus, it appears that the accumulation of sinapate derivatives around the hydathode of cotyledons is a natural occurrence in seedling development and that ugt80B1 mutants retain this pattern in a greater proportion of the cotyledon during development. The cotyledon hydathode from ugt80A1,B2 seedlings was stained with an iodine mixture (I2:KI) to determine whether starch accumulation is altered in this region. Reminiscent of the DPBA staining (Supplemental Fig. S7B), the double-mutant cotyledon displayed a distinct staining pattern around the hydathode region that was markedly more pronounced than wild-type hydathode staining. High-magnification imaging of the hydathode region revealed an altered morphology of cells in this region in double-mutant seedlings.

SGs Are Critical for Normal Cell Morphology of the Seed Coat and Deposition of Lipid Polyesters as Analyzed by Electron Microscopy and Gas Chromatography-Mass Spectrometry

Scanning electron microscopy (SEM) was applied to ascertain possible alterations in the morphology of cells within the seed epidermis (Fig. 5, A–D). Severe defects in cell morphology were evident in double-mutant seed (Fig. 5, B–D). In addition to smaller seed size, approximately one-third of seed displayed a sunken region extending from the hilum (Fig. 5B). Further examination by transmission electron microscopy (TEM) was performed to visualize the ultrastructure of the seed coat in the mutants. Strikingly, the electron-dense outer layer covering the wild-type seed coat was found to be absent in ugt80B1 and double mutant (Fig. 5, E and F). To understand the changes in development, the same analysis was applied at the developmental stage when wild-type seeds can first repel tetratrazolium salts. At this stage wild-type seed already displayed an electron-dense cuticle layer covering the seed coat, and were beginning to form columella. By contrast, the cuticle layer was greatly diminished in the double mutant, and the columella were less prominent (Fig. 5D). The cellular morphology in the mutant was strikingly different from wild type: Aberrant dispersed electron-dense regions that are observed in the cytosol may represent an abnormal accumulation of suberin, wax, or cutin that failed to be transported to the outer surface of the seed. The failure to form columella was consistent with the SEM data (Fig. 5D) and indicates that this defect arose during embryonic development (Fig. 2).

Next, we examined the hilum region of the wild-type seed compared with mutant by autofluorescence analysis using a broad-spectrum UV light source, since autofluorescence around the hilum reflects accumulation of suberin (Beisson et al., 2007). The results indicate that the hilum region of both the ugt80B1 and double mutant exhibit reduced suberization, which appears as a bright autofluorescent signal in ugt80A2 and wild-type seed (Fig. 5, G and H). Consistent with these observations, analysis of lipid polyester monomers from seeds of the ugt80B1 mutant in comparison to wild type showed an overall 50% reduction in total aliphatics (Fig. 6). The vast majority of the 45 polyester monomers identified were significantly reduced in the ugt80A2,B1 mutant, including the C22 and C24 very-long-chain ω-hydroxy fatty acids typical of suberin. The reduction in polyester
monomers was however not equivalent. For example, the C24 \( \alpha,\omega \)-hydroxy fatty acid was reduced 2-fold and the C24 \( \alpha,\omega \)-diacid remained almost unchanged although both monomers are known to be mostly localized to the outer integument of the seed coat (Molina et al., 2008). Interestingly, the 9,10,18-trihydroxyoleate cutin monomer, which is largely specific to the embryo (Molina et al., 2006), was 60% reduced. This observation, together with the defects apparent in the cutin-like electron-dense layer of the seed coat surface (Fig. 5F), indicates that the deposition of cutin polymer is also affected.

**DISCUSSION**

Here we used a reverse-genetic approach to explore the functions of UDP-Glc:sterol glucosyltransferase in plants. T-DNA mutations in \( \text{UGT80A2} \) (At3g07020) and \( \text{UGT80B1} \) (At1g43620) were identified and characterized in addition to the corresponding double mutant. Sterol derivatives SG + ASG were significantly reduced in \( \text{ugt80A2} \) and \( \text{ugt80B1} \) single mutants (Supplemental Table S1). Hence, both UGT80A2 and UGT80B1 function in catalyzing the glycosylation of 24-alkyl-\( \Delta5 \)-sterols in Arabidopsis. Moreover, FS + SE increased 26% in \( \text{ugt80A2,B1} \) siliquae + inflorescence tissue relative to wild type. In the same tissue SG + ASG content decreased 22-fold in \( \text{ugt80A2,B1} \) relative to wild type (Fig. 1). These data implied a feedback relationship between the FS + SE content relative to SG + ASG in certain tissues. Phenotypic examination revealed that \( \text{ugt80B1} \) caused the most notable phenotypes. Based on alleleism tests, \( \text{ugt80B1} \) corresponds to the previously unannotated \( \text{tt15} \) mutant (Focks et al., 1999). HPLC analysis of flavanols and condensed tannins performed independently showed aberrant condensed tannin synthesis in \( \text{ugt80B1} \) (Isabelle Debeaujon, personal communication), confirming staining results. The accumulation of suberin around the hilum region of the wild-type Arabidopsis seed, where the funiculus dissociates the seed from the parent, was ablated in the \( \text{ugt80B1} \) mutant (Fig. 5, G and H). Reduction in the amount of suberin observed visually by autofluorescence was confirmed by gas chromatography-mass spectrometry (GC-MS) analysis (Fig. 6). But moreover, GC-MS analysis also revealed that many of the structurally diverse lipid polyester precursors to form suberin and cutin in the seed.

Other transparent testa mutants have been characterized by forward genetics in Arabidopsis and these fall broadly into two categories: transcription factors and genes catalytically involved in the flavanoid biosynthesis pathway (Debeaujon et al., 2003). An atypical mutation leading to a transparent testa phenotype was found to map in a gene for plasma membrane H+-ATPase (AHA10; Baxter et al., 2005). This mutation caused a 100-fold decrease in proanthocyanidins (PAs) in seed endothelial cells. The deficiency in PA in \( \text{aha10} \) mutants was correlated with a defect in biogenesis of a large central vacuole (Baxter et al., 2005), yet the reason for the lack of PA accumulation was not clear. Hence, like \( \text{ugt80B1} \), the \( \text{aha10} \) mutant appears to be distinct from other transparent testa mutants that ablate catalytic functions within the flavanoid pathway. \( \text{aha10} \) and \( \text{ugt80B1} \) may represent a novel class of mutants that indirectly cause a transparent testa phenotype due to membrane-related defects. In studies with animal cells, the gradient of SG and ASG content has been correlated with membrane thickness and the sorting of membrane proteins based on the lengths of the transmembrane domains (Bretscher and Munro, 1993). Alteration of the sterols in the membrane may result in aberrant behavior of an assortment of membrane proteins. In this scenario, alterations in the physical properties of the membrane dynamics such as reduced rate of exchange of SG and ASG between the monolayer halves of a bilayer may affect some aspect of flavanoid synthesis, such as transport or accumula-
tion. Among proteins directly involved in flavanoid biosynthesis, chalcone synthase and chalcone isomerase are thought to be membrane anchored (Jez et al., 2000). Also, as-yet-unidentified proteins are presumably involved in the transport of flavanoids into vacuoles.

The sterol content of plant membranes has been observed to change in response to environmental conditions and it has been suggested that alterations in the sterol composition of the plasma membrane may play a role in the cold acclimation process (Patterson et al., 1993). Moreover, gene expression data from available microarray experiments (Genome Cluster Database) suggest that UGT80B1 transcripts are slightly up-regulated by cold stress. The mutants described here provided an opportunity to test this hypothesis with respect to SG and ASG. We investigated the adaptive response to temperature stress but were unable to detect a significant difference between mutants and wild type. Thus, although sterol content of membranes in Arabidopsis was modulated in part by SG and ASG synthesis, loss of these membrane components did not appear to adversely affect growth or viability at low temperatures. The slightly reduced growth rate of the mutants at all temperatures indicates that SGs are important for growth and development, as might be expected from their widespread presence in plants. However, this role appears to be beneficial rather than crucial.

A significant motivation for the isolation of the ugt80A2 and ugt80B1 mutants was to test the postulate that SG functions in cellulose biosynthesis. The elongation defects of double-mutant embryos (Fig. 2) suggested possible defective cell wall biogenesis. Peng et al. (2002) observed the tight association of SSG with an amorphous form of cellulose and speculated that SSG may be a primer for the initiation of cellulose. We tested the hypothesis by measuring cellulose content in leaves, stems, roots, flowers, siliques, and trichomes of the double mutant but found no significant differences between mutant and wild type in cellulose content, and only minor alterations in the content of the sugars that comprise the other cell wall polysaccharides (Fig. 3, A and B). Therefore, if SSG biosynthesis by UGT80A2 or UGT80B1 has a role in cellulose biosynthesis, it was a dispensable role or was fulfilled by residual levels of SSG. The low residual level of SG in the double mutant also prevented a definitive answer to the question of whether plants require SG for viability and/or cellulose synthesis since it is possible that plants require only a trace amount of SSG. A possible source of residual SSG may arise from the activity of glucosylceramide synthase, which Hillig et al. (2003) demonstrated was capable of catalyzing the glycosylation of sterols in vitro.

Uptake of tetrazolium salt occurred far more readily in ugt80B1 mutants, suggesting less control of seed coat permeability (Fig. 4B). A plausible explanation for the salt-uptake phenotype in the ugt80B1 mutant may be a direct result of reduced seed coat suberization in the hilum region (Fig. 4, G and H) and/or reduced cuticle formation at the surface of the outer integument. Cutin-like monomers are also known to be present in the inner integument and in the embryo (Molina et al., 2006, 2008). Lipid polyesters (cutin, aliphatic suberin) are structurally related biopolymers that are involved in controlling water relations (Pollard et al., 2008) and seem to have conserved features in their mechanisms of biosynthesis and export to the cell wall (Li et al., 2007). However, there was no obvious explanation as to why the reduction in SG and ASG impacted hilum suberization as well as seed coat and embryo cuticle formation. Thus, we speculate that SG and ASG are necessary membrane components required for efficient lipid polyester precursor trafficking or export into the apoplast in plant seeds.

MATERIALS AND METHODS

Plant Material and Growth Conditions

All Arabidopsis (Arabidopsis thaliana) lines used in this study were of the Wassilewskija (WS)-O ecotype. Seeds were surface sterilized using 30% bleach solution and stratified for 3 d in 0.15% agar at 4°C. For phenotypic analysis and growth assays plants were exposed to light for 1 h and grown in either continuous light (200 mmol m^{-2} s^{-1}) or complete darkness at 22°C on plates containing 0.5× Murashige and Skoog mineral salts (Sigma) and 1% agar.

Identification of T-DNA Insertions in UGT80A2 and UGT80B1

Homozygous T-DNA insertion mutations in both UGT80A2 and UGT80B1 were identified by screening the Wisconsin T-DNA collection by PCR as described in Sussman et al. (2000). Screening primers for UGT80A2 result in amplification of 440- and 581-bp products in mutant and wild type, respectively, with T-DNA primers JL214 5’-GCTGCGGACATCTACATTTTTG-3’, UGT80A2H248rev 5’-CTTCCCTGCGAGAGATTTTGTCA-3’, and UGT80A2H248com 5’-AGCAGACCGCAATTTCAGATA-3’. Screening primers for UGT80B1 result in 595- and 455-bp mutant and wild-type products using T-DNA primer JL214 5’-GCTGCGGACATCTACATTTTTG-3’, UGT80B1rev 5’-ATTTCAATTAGAAGACATTTACAG-3’, and UGT80B1con 5’-AAGAATTGTGAAGTGGGTGATGG-3’. A 55°C annealing temperature was applied. Homozygous lines for ugt80A2 and ugt80B1 were crossed and F2 progeny were screened for homozygous T-DNA insertions in both alleles.

SEM

All imaging was performed on a Quanta 200 (FEI Company) scanning electron microscope fit with a 1,000-mm gaseous secondary electron detector. Whole-seed specimens were mounted in cryo gel (Ted Pella, Inc.) on a temperature-controlled stage set at 1°C and pressure was maintained at 652 Pa. Image annotation and linear contrast optimization was performed in Adobe Illustrator CS2.

TEM

For analysis of mature seeds, seeds were dried after release from siliques. The seeds were placed at 4°C for 24 h in a 10 μM solution of abscisic acid to hydrate the seeds without inducing germination. Young seeds were extracted from immature siliques and were exposed to tetrazolium salts. Wild-type seeds that resisted staining with the salts and mutant seeds of an identical time point were selected for further electron microscopy processing. All fixation and embedding steps were performed through microwave processing. Samples were fixed in glutaraldehyde and dehydrated with ethanol increasing the concentration by 10% up to 100%. They were then infiltrated with a resin acetone mixture in steps of 1 part resin 2 parts acetone, 1 part resin 1 part acetone, and 2 parts resin 1 part acetone, after which the samples were polymerized in 100% resin overnight in 55°C. The samples were then...
mount, sectioned, and stained using 2% uranyl acetate in methanol and imaged with a Tecnai 12 TEM (FEI).

Histochemical Analysis

Tetrazolium Salt Uptake

Ability of seeds to uptake salt was tested by placing whole seeds in an aqueous solution of 1% (w/v) tetrazolium red (2,3,5-triphenyltetrazolium) at 30°C for 4 to 24 h. Seeds were removed from the solution and imaged by light microscopy.

Ruthenium Red

Ruthenium red (Sigma) was dissolved in water at a concentration of 0.03% (w/v) and seeds from wild type and mutants were imbibed in this solution for 30 min at 25°C. Seeds were removed from the imbibition solution and observed under a light microscope (Debeaujon et al., 2001, 2003).

DPACA

Seedlings were stained for 15 min using saturated (0.25%, w/v) DPACA with 0.005% (v/v) Triton X-100 and were visualized with an epifluorescent microscope equipped with a fluorescein isothiocyanate filter (excitation 450–490 nm, suppression LP 515 nm).

DMACA

Seeds were stained with DMACA reagent (2% [w/v] DMACA in 3 m HCl/50% [w/v] methanol) for one week, and then washed three times with 70% (v/v) ethanol. The stained pools were then examined using light microscopy.

Ultraviolet-Induced Fluorescence Analysis of Suberin Localized at the Seed Hilum

Seeds from wild-type WS-O, ugt80A2, ugt80B1, and the double mutant were examined under UV illumination for analysis of characteristic autofluorescence in the region of the seed hilum, reflecting suberin deposition (Beisson et al., 2007). Individual specimens were visualized under UV fluorescence using a compound microscope (Leitz DMBB, Leica).

Sterol Analysis

Sterols and sterol conjugates sterlyls (SEs, SG, and ASG) were isolated from wild-type, ugt80A2, ugt80B1, and double-mutant plant tissues. Briefly, the dried plant material was ground with a blender in a mixture of dichloromethane/methanol (2:1, v/v). Metabolites were extracted under reflux at 70°C. The dried residue was separated by thin-layer chromatography (Merck F254 0.25-mm thickness silica plates) using dichloromethane/methanol/water (85:15:0.5, v/v/v) as developing solvent (one run) and authentic standards as mobility references. SE, FSE, SG, and ASG were scraped off the plates. The dried residues of SE were saponified in methanolic KOH (6%) under reflux at 90°C for 1 h. The dried residues of SG or ASG were submitted to an acidic hydrolysis in an ethanolic solution of sulfuric acid (1%). Sterols were extracted from hydrolytes after addition of half a volume of water with 3 times 1 volume of n-hexane. Dried residues were subjected to an acetylation reaction for 1 h at 70°C with a mixture of pyridine/acyclic anhydride/toluene (1:1:1, v/v/v). After evaporation of the reagents, sterol acetates were resolved as one band in a thin-layer chromatography using dichloromethane as developing solvent. Steryl acetates were analyzed and quantified in GC-flame ionization detector (FID) using cholesterol as an internal standard. Structures were confirmed by GC-MS.

Cell Wall Preparation and Analysis

Alditol acetate derivatives of the neutral sugars were measured on ball-milled (2 h) 4-week-old primary stem tissue. Cellulose contents were measured colorimetrically and total uronic acid content was determined by GC using 500 mg (dry weight) of ball-milled material as described (Blumenkrantz and Asboe-Hansen, 1973; McCann et al., 1997).

Analysis of Seed Lipid Polyesters

Soluble lipids were removed from 250 to 350 mg mature seeds using the procedure described by Molina et al. (2006). The dry residue was depolymerized using acid-catalyzed methanolysis (5% [v/v] sulfuric acid in methanol for 2 h at 85°C). C17:0 methyl ester and C15 α-pentadecanolate were used as internal standards. Monomers were extracted with 2 volumes of dichloromethane and 1 volume of 0.9% (w/v) NaCl. After aqueous washing, the organic phase was dried over anhydrous sodium sulfate and evaporated under nitrogen gas. The monomers were derivatized by acetylation or silylation and separated, identified, and quantified by GC-MS. Splitless injection was used, and the mass spectrometer was run in scan mode over 40 to 500 atomic mass units (electron impact ionization), with peaks quantified on the basis of their total ion current. Details of chromatographic conditions and aliphatic and aromatic monomer identifications are described in Molina et al. (2006).

Whole Mounts of Embryos

Whole-mount preparations were done by clearing ovaries from wild type and mutants in chloral hydrate solution made from an 8:3:1 mixture of chloral hydrate, water, and glycerol. Ovules were pooled from siliques into drops of chloral hydrate solution on microscope slides, followed by 24-h incubation at room temperature. Histological analysis and microscopy of ovules were performed with a Zeiss Axioskop 2. Digital images of embryos were captured with an AxioCam HRc with AxioVision Rel 4.3 software (Carl Zeiss GmbH). Images were processed with Adobe Photoshop 8.0 and Illustrator 11.0.0 software (Adobe Systems Inc.).
