The chloroplast thylakoid ATP/ADP carrier (TAAC) belongs to the mitochondrial carrier superfamily and supplies the thylakoid lumen with stromal ATP in exchange for ADP. Here, we investigate the physiological consequences of TAAC depletion in Arabidopsis \textit{(Arabidopsis thaliana)}. We show that the deficiency of TAAC in two T-DNA insertion lines does not modify the chloroplast ultrastructure, the relative amounts of photosynthetic proteins, the pigment composition, and the photosynthetic activity. Under growth light conditions, the mutants initially displayed similar shoot weight, but lower when reaching full development, and were less tolerant to high light conditions in comparison with the wild type. These observations prompted us to study in more detail the effects of TAAC depletion on photoinhibition and photoprotection of the photosystem II (PSII) complex. The steady-state phosphorylation levels of PSII proteins were not affected, but the degradation of the reaction center II D1 protein was blocked, and decreased amounts of CP43-less PSII monomers were detected in the mutants. Besides this, the mutant leaves displayed a transiently higher nonphotochemical quenching of chlorophyll fluorescence than the wild-type leaves, especially at low light. This may be attributed to the accumulation in the absence of TAAC of a higher electrochemical H\textsuperscript{+} gradient in the first minutes of illumination, which more efficiently activates photoprotective xanthophyll cycle-dependent and independent mechanisms. Based on these results, we propose that TAAC plays a critical role in the disassembly steps during PSII repair and in addition may balance the trans-thylakoid electrochemical H\textsuperscript{+} gradient storage.

In plants, the chloroplast thylakoid membrane is the site of light-driven photosynthetic reactions coupled to ATP synthesis. There are four major protein complexes involved in these reactions, namely, PSI, PSII, the cytochrome b\textsubscript{6}f, and the H\textsuperscript{+}-translocating ATP synthase (for review, see Nelson and Ben-Shem, 2004). The photosystems and the cytochrome b\textsubscript{6}f complex also contain redox components and pigments bound to protein subunits. Their synthesis, assembly, optimal function, and repair during normal development and stress require a number of transport and regulatory mechanisms. In this context, the water-oxidizing PSII complex composed of more than 25 integral and peripheral proteins attracts special attention since its reaction center D1 subunit is degraded and replaced much faster than the other subunits under excess and even growth light conditions (for review, see Aro et al., 2005). Thus, the D1 protein turnover is the major event in the repair cycle of the PSII complex and occurs subsequently to the inactivation of PSII electron transport. D1 degradation is most likely performed by thylakoid FtsH and Deg proteases, operating on both sides of the thylakoid membrane (Lindahl et al., 2000; Haussühl et al., 2001; Silva et al., 2003; Kapri-Pardes et al., 2007). The PSII repair cycle is regulated by reversible phosphorylation of several core subunits (Tikkanen et al., 2008).

ATP is produced as a result of the light-driven photosynthetic reactions in the thylakoid membrane and mainly utilized in the carbon fixation reactions occurring in the soluble stroma. Besides this, ATP also drives several energy-dependent processes occurring on the stromal side of the thylakoid membrane, including phosphorylation, folding, import, and degradation of proteins. Furthermore, experimental evidence for ATP transport across the thylakoid membrane and nucleotide metabolism inside the luminal space has been reported (Spetea and Thuswaldner, 2008; Spetea and Schoefs, 2010). The protein responsible for the thylakoid ATP transport activity has been identified in Arabidopsis (Arabidopsis thaliana) as the product of the At5g01500 gene and functionally characterized in Escherichia coli as an ATP/ADP exchanger (Thuswaldner et al., 2007).

In the same report, it has been demonstrated that TAAC transports ATP from stroma to lumen in exchange for ADP, as based on radioactive assays using thylakoids isolated from Arabidopsis wild-type plants and a T-DNA insertion knockout line (named taac). Furthermore, TAAC was shown to be mainly expressed in photosynthetic tissues with an up-regulation during greening, senescence, and stress (e.g. high light) conditions, implying a physiological role during thylakoid biogenesis and turnover.

The ATP translocated by TAAC across the thylakoid membrane is converted to GTP by the luminal nucleoside diphosphate kinase III; GTP can then be bound and hydrolyzed to GDP and inorganic phosphate by the PsbO protein, a luminal extrinsic subunit of the PSII complex (Spetea et al., 2004; Lundin et al., 2007a). The anion transporter 1 from Arabidopsis has been proposed to export the stroma the phosphate generated during nucleotide metabolism in the thylakoid lumen (Ruiz Pavón et al., 2008). Between the two PsbO isoforms in Arabidopsis, it has recently been reported that PsbO2 plays an essential role in D1 protein turnover during high light stress and that it has a higher GTPase activity than PsbO1 (Lundin et al., 2007b, 2008; Allahverdiyeva et al., 2009). The precise mechanism of PsbO2-mediated PSII repair is not known. Nevertheless, the requirement of GTP for efficient proteolytic removal of the D1 protein during repair of photoinactivated PSII was previously reported (Spetea et al., 1999). Furthermore, it has been proposed that the PsbO2 type of PSII complexes undergo more efficient repair. This has been attributed to the PsbO2-mediated GTPase activity that induces PsbO2 release from the complex, thus facilitating the next steps in the repair process, namely, dissociation of the CP43 subunit and proteolysis of the D1 subunit (Lundin et al., 2007b, 2008).

TAAC may represent the missing link between ATP synthesis on the stromal side of the thylakoid membrane and nucleotide-dependent reactions in the luminal space. The taac mutant provides an interesting tool to study whether there are any regulatory networks between the activity of TAAC and PSII repair. Based on phenotypic characterization of two different T-DNA insertion lines of the TAAC gene, we report in this article that the PSII repair cycle is malfunctioning in the absence of TAAC and that the thermal photo-protection is faster activated during light stress.

RESULTS
PSII Activity under Growth Light Conditions

The taac knockout mutant, initially characterized by Thuswaldner et al. (2007), was obtained from the Institut National de la Recherche Agronomique Public-Lines collection (FLAG_443D03, Wassilewskija [Ws] ecotype) and is shown here to contain a single T-DNA insertion (Supplemental Fig. S1). A second homozygous taac mutant identified from Syngenta T-DNA insertion lines collection (SAIL_209_A12, Columbia ecotype) is described in Supplemental Figure S2.

At an irradiance of 120 μmol photons m$^{-2}$ s$^{-1}$ (GL), the taac mutants grew initially with the same rate as the wild-type plants of the respective ecotype, but then slower and had significantly less (20%) leaf biomass compared to the wild type (Fig. 1, A and B; Supplemental Fig. S3, A and B). When examined with electron microscopy, structurally normal chloroplasts containing starch grains and thylakoid membranes with typical stacked grana were found in all types of plants (Fig. 1C; Supplemental Fig. S3C). Plastid length and width ranged in all samples between 5 and 6 and 2 to 3 μm, respectively. The studied plastid profiles contained 58 to 61 grana on average, and there was no large difference between taac and wild-type plants in this respect. Similarly, no large difference was found in height (number of appressed thylakoid lamellae per granum) or length of the grana between the mutants and their respective ecotypes. This indicates that depletion of TAAC does not influence chloroplast and thylakoid ultrastructure under average, nonstressful conditions.

The chlorophyll (Chl) content of whole leaves (expressed per leaf fresh weight or per leaf surface unit) and Chl $a/b$ ratio were not significantly affected by the deficiency of TAAC in the mutant compared to the wild type (Table I; Supplemental Table S1). The maximum quantum yield of PSII photochemistry was the same in wild-type and taac leaves ($F_{m}/F_{m} = 0.8$). Similar steady-state rates of oxygen evolution were measured in thylakoid membranes in the presence of the PSII acceptor phenyl-p-benzoquinone. Nevertheless, addition of NH$_4$Cl has resulted in significantly higher rates of oxygen evolution in the mutant compared with the wild type. The observed difference is consistent with the existence of the mutant of an overall higher capacity for PSII electron transport per unit Chl. A stimulatory effect of NH$_4$Cl on the electron transport
with the addition of 10 mM NH4Cl (uncoupler) or in the presence of 100

Figure 1. Comparison of the taac mutant with wild-type Arabidopsis
in isolated thylakoid membranes has previously been
attributed to an increased dissipation of H$^+$ gradient
across thylakoids and uncoupled photophosphorylation (McCarty, 1980; Thomasset et al., 1984). Therefore, our results may indicate a higher H$^+$ gradient existing across the thylakoid membrane in the mutant compared to the wild type. The activities of the whole
in isolated thylakoid membranes were indistinguishable, based on the rates of oxygen consumption in the presence of methyl viologen (and sodium azide; Table I; Supplemental Table S1). Furthermore, no significant differences were found in the rates of cyclic electron transport based on the calculated halftime ($t_{1/2}$) for the P$^{700+}$ re-reduction in darkness (Table I; Supplemental Table S1). Finally, the rates of CO$_2$ fixation were similar in taac and wild-type leaves (Supplemental Fig. S4) and are therefore not able to explain the reduced biomass of the mutant.

The leaves of wild-type and taac plants exhibited a
typical O-J-I-P fluorescence induction curve (Supple-
mental Fig. S5; Strasser et al., 1996; Tsimilli-Michael et al., 2000). The shape of the curve, the values obtained for the relative variable fluorescence at the J-step ($F_J$) between 0.36 and 0.47, and the initial slope ($M_0$) between 0.78 and 1.26 are typical for healthy plants (Tsimilli-Michael et al., 2000). The analysis of the O-J-I-P curves allows the determination of the fate of the absorbed energy (parameter ABS): part of the excitation energy is dissipated in the antenna of the light-harvesting complex II (LHCII; parameter DI$_0$) as heat and/or fluorescence, and the remaining is channeled to the reaction centers (parameter TR$_0$). There, the energy is converted to redox energy by reducing the first stable quinone electron acceptor Q$_A$, while the reaction center (RC) Chl P$^{680+}$ is oxidized, thus creating an electron transport (parameter ET$_0$) within the photosynthetic apparatus (Supplemental Fig. S6). Table II compares the PSII behavior in wild-type and taac leaves using energy fluxes expressed per RC of the sample. The ABS/RC parameter was shown to be a measure of the antenna size (Strasser et al., 1996). The obtained similar values in taac and the wild type are in line with the absence of significant difference in the Chl a/b ratio (Table I) and the only slight modifi-
cation in the Chl and xanthophyll levels (see below).
Furthermore, calculations of the flux of energy reaching the RCII (TR$_0$) and of the flux of energy dissipated as heat and/or fluorescence in the an-
tenna, when the first excitons closed all the RCII (DI$_0$) indicated no significant differences between the two types of plants (Table II). Taken together, these data indicate a similar distribution of energy fluxes at PSII level.

$^a$Light-saturated rate of oxygen evolution measured in thylakoid membranes in the presence of 0.5 mM phenyl-p-benzoquinone (pPBQ) without or with the addition of 10 mM NH$_4$Cl (uncoupler) or in the presence of 100 $\mu$m methyl viologen (MV) and 5 mM sodium azide. $^b$Cyclic electron transport was measured as halftime ($t_{1/2}$) for P$_{700+}$ re-reduction.
Nonphotochemical quenching of Chl fluorescence (NPQ) is an important photoprotective mechanism minimizing the photooxidative damage to the photosynthetic apparatus (for review, see Horton et al., 2008). To test whether the deficiency of TAAC affects photoprotection, the kinetics of NPQ formation were recorded for 20 min at photosynthetic active radiation (PAR) of 300, 600, and 1,250 µmol m$^{-2}$ s$^{-1}$ in the two taac mutants and the respective background plants (Fig. 2; Supplemental Fig. S3C). The initial phase was transient with NPQ reaching a maximum 120 to 200 s after the first saturating pulse, as described by D’Haese et al. (2004). Nevertheless, the amplitude of this phase and the rate of NPQ formation were higher in taac mutants at the three tested light intensities. The second phase during the remaining illumination period of 20 min was slow and displayed no significant differences in the levels of NPQ between the mutants and the respective wild-type ecotype. The induced NPQ component was rapidly reversible and decayed during the dark period with similar kinetics and extent in the wild-type and taac plants (Fig. 2). Taken together, these results indicate that the mutants are more efficient in activating the formation of NPQ. Although of different ecotypes, the SAIL_209_A12 mutant showed phenotypes identical with FLAG_443D03 (Supplemental Fig. S3), chosen for detailed physiological and biochemical characterization (see below).

PSII Activity under High Light Conditions

The wild-type Ws and FLAG 443D03 taac plants were grown under GL conditions for 28 d and then under high light (HL; 950 µmol photons m$^{-2}$ s$^{-1}$) conditions for additional 28 d, maintaining the diurnal cycle. Leaf samples were collected in the course of their growth to measure the maximum quantum yield of PSII photochemistry ($F_{m'}/F_{m}$). Similar values (0.8) during day 0 of HL growth, followed by a slow decrease until day 4 (0.72), were measured in both types of plants (Fig. 3A). This parameter continued to decrease until day 7 in the mutant (0.62), whereas at the same time point the wild-type plants almost fully restored their PSII activity (0.78). The mutant fully restored the activity only on day 14 (0.8). Taken together, the pattern observed for $F_{m'}/F_{m}$ indicates an enhanced susceptibility to high light for the mutant compared to the wild type. The slower recovery of PSII activity was at the expense of plant growth since the mutant displayed poor health, as shown in Figure 3B photos, taken after 28 d of HL conditions.

Leaf Pigment Analysis and Xanthophyll Cycle

The amplitude of the initial rapid phase of NPQ formation depends on the accumulation of H$^{+}$ in the thylakoid lumen and on the pigment and protein composition of the antenna (Horton et al., 2008). Acidification of the lumen leads to activation of violaxanthin de-epoxidase, which converts violaxanthin to antheraxanthin and finally to zeaxanthin as part of the xanthophyll cycle (for review, see Hieber et al., 2000; Horton et al., 2008). To investigate the mechanism behind the faster response of the mutant when it comes to NPQ (Fig. 2), we analyzed the wild-type and

| Table II. Comparison of energy fluxes in the wild-type (Ws) and taac plants |
|---------------------------------|-----------------|-----------------|
| Energy Flux | Ws | taac |
| ABS/RC | 2.815 ± 0.065 | 2.607 ± 0.074 |
| TR$_{0}$/RC | 2.198 ± 0.270 | 2.125 ± 0.520 |
| DI$_{0}$/RC | 0.624 ± 0.192 | 0.483 ± 0.024 |
| ET$_{0}$/RC | 1.182 ± 0.044 | 1.182 ± 0.097 |

The amplitude of the initial rapid phase of NPQ formation depends on the accumulation of H$^{+}$ in the thylakoid lumen and on the pigment and protein composition of the antenna (Horton et al., 2008). Acidification of the lumen leads to activation of violaxanthin de-epoxidase, which converts violaxanthin to antheraxanthin and finally to zeaxanthin as part of the xanthophyll cycle (for review, see Hieber et al., 2000; Horton et al., 2008). To investigate the mechanism behind the faster response of the mutant when it comes to NPQ (Fig. 2), we analyzed the wild-type and

![Figure 2. Kinetics of NPQ formation. Chlorophyll fluorescence of leaves detached from 16-h dark-adapted wild-type (Ws) and taac plants was recorded during a 20-min exposure to light (white bar) of 300, 600, or 1,250 µmol photons m$^{-2}$ s$^{-1}$, followed by 15-min recovery in darkness (black bar). Saturating pulses (1.0 s) of actinic light were applied to determine the maximum fluorescence yield $F_{m}$ or $F_{m'}$: NPQ was calculated from fluorescence data as $(F_{m} - F_{m'})/F_{m}'$.](https://www.plantphysiol.org)
taac plants in terms of pigment composition and interconversion of the xanthophylls, measured as de-epoxidation ratio.

Pigment analysis (neoxanthin, violaxanthin, lutein-5,6-epoxide, antheraxanthin, lutein, zeaxanthin, Chl b, Chl b', Chl a, Chl a', pheophytin a, and β-carotene) was performed from the leaves of the two types of plants, and the composition was found typical for healthy green leaves (Schoefs et al., 1996). The most abundant pigments were lutein, Chl a, and Chl b (Fig. 4A). Lutein-5,6-epoxide and Chl epimers were only present in traces and therefore were not quantified. Generally, the pigments were slightly but less abundant in the taac than in the wild-type leaves. At a PAR of 120 μmol photons m⁻² s⁻¹, the xanthophyll cycle was only weakly activated in both the wild type and mutant, as indicated by the low values of the de-epoxidation ratio (Fig. 4B). As PAR intensity increased, the xanthophyll cycle was progressively activated, and notably, to a much higher extent in the mutant than in the wild type. The de-epoxidation reaction saturated at approximately 1,250 μmol photons m⁻² s⁻¹ in the wild type but not in the taac leaves.

NPQ induction results from an excess of light at the level of PSII. It involves a response to the trans-thylakoid pH gradient, the xanthophyll cycle, the PsbS protein, and other, yet undefined aspects of photoinhibition. It has been postulated that the structural unit of NPQ consists of LHCCI proteins and the PsbS protein and is formed upon protonation and binding of xanthophyll cycle carotenoids (Horton et al., 2008). Therefore, it was of great interest to examine the effect of nigericin and dithiothreitol (DTT), the well-known inhibitors of the trans-thylakoid pH gradient and of violaxanthin de-epoxidation, respectively. As shown in Figure 4C, in nigericin-treated leaves, the NPQ no longer displayed two phases but a continuous and weak increase with the increase of light intensity. The kinetics between the taac and wild-type plants were undistinguishable. Notably, DTT-treated leaves still display an initial rapid phase of NPQ formation. Like in control-treated leaves, both the amplitude and the rate of induction of this phase are higher in the taac mutant, whereas the steady-state NPQ levels are similar to the wild type. Since the relative amounts of PsbS and LHCCI proteins were similar in the two types of plants (see below), these results collectively suggest that the trans-thylakoid pH gradient is the major factor responsible for the higher efficiency of NPQ formation observed in taac plants (Fig. 2).

Levels of Thylakoid Photosynthetic Proteins and PSII Phosphoproteins

Reduced weight was observed for fully developed taac plants grown under GL conditions. It was therefore tested whether the deficiency of TAAC changes the protein content in isolated thylakoid membranes. Western-blot analysis was performed using antibodies directed against various proteins of the PSII complex (CP43, D1, D2, PsbO, PsbP, Lhcb1, Lhcb2, and PsbS) as well as representative proteins in the ATP synthase (β-subunit of CF1) and the PSI complex (PsaA/B). Based on visual inspection of the western blots, no differences in the levels of analyzed proteins were apparent in taac compared to the wild-type thylakoids (Fig. 5A).

Phosphorylation of PSII proteins is an important step in the repair cycle of the complex (Tikkanen et al., 2008). To test whether the steady-state phosphorylation levels of PSII proteins were affected in the taac mutant, we isolated thylakoids from plants, which were dark adapted for 16 h or illuminated for 3 h either with GL or HL, and performed western blotting using an antiphosphothreonine antibody (Lundin et al., 2007b, and refs. therein). Under all three tested conditions, the levels of immunodetected phosphorylation of the PSII core proteins and the LHCCI proteins were similar between the taac and wild-type thylakoids (Fig. 5B).
These results indicate that depletion of TAAC does not influence the activity of thylakoid-associated PSII kinases and phosphatases.

Susceptibility to Photoinhibition of PSII

The reduced tolerance of the taac mutant during growth under HL conditions (Fig. 3) prompted us to test whether TAAC depletion influences the D1 protein degradation step during repair of PSII complex. To this end, the leaves detached from the taac and wild-type plants were illuminated for 1 and 3 h in the absence and presence of lincomycin, which blocks the synthesis of chloroplast-encoded proteins, including D1. The $F_v/F_m$ parameter, used to monitor the maximal PSII activity, was recorded from intact leaves, whereas western blotting of isolated thylakoids with anti-D1 antibodies was performed to follow the D1 protein levels. When the wild-type and taac leaves were illuminated with GL in the absence or presence of lincomycin, no dramatic difference in the decay of $F_v/F_m$ was observed (Fig. 6A). As expected, when protein synthesis was inhibited with lincomycin during the HL treatment, the PSII RCs of the wild type turned out to be more prone to photodamage, as revealed by a faster decrease in the $F_v/F_m$ parameter. Notably, under the HL conditions, the PSII RCs of taac were activated with similar rates in the absence and presence of lincomycin and to a similar extent (50%) as in the wild type in the presence of lincomycin. The D1 protein degradation was found blocked in all studied conditions in the mutant compared to the wild type where a clear loss of the protein was observed during both GL and HL in the presence of lincomycin (Fig. 6B). When PSII activity was measured in 3 h HL-treated leaves in the absence of lincomycin during subsequent 80 min of incubation in darkness, $F_v/F_m$ was partially restored in the wild type (0.73), but slower and to a much lower extent in the mutant (0.59; Fig. 6C), supporting the malfunction in the PSII repair. Next, we preilluminated leaves for various periods of time at HL, allowed 5 min dark adaptation, and subsequently recorded NPQ induction curves at 1,250 μmol photons m$^{-2}$ s$^{-1}$ (Supplemental Fig. S7). The steady-state levels of NPQ were reached within 60 s of illumination in both wild-type and the mutant leaves (data not shown) and similarly decreased with the duration of the preillumination time (Supplemental Fig. S7). Taken together,

Figure 4. Pigment composition and xanthophyll cycle in Ws ecotype plants and the taac mutant. A, Leaves from plants grown at an irradiance of 120 μmol photons m$^{-2}$ s$^{-1}$ were detached at the end of the dark period, and the pigment composition was determined by HPLC. Amounts of main pigments are expressed relative to Chl a ± SD ($n = 17$). B, Leaves were illuminated with PAR of intensities ranging between 53 and 1,952 μmol photons m$^{-2}$ s$^{-1}$. The time of illumination was 20 min for PAR intensities <1,000 μmol photons m$^{-2}$ s$^{-1}$ and reduced to 10 min for higher PAR intensities. Following illumination, pigments were extracted and analyzed by HPLC. Activity of the xanthophyll cycle was determined as de-epoxidation ratio (DR) ± SD ($n = 3–4$ for each point). DR = (antheraxanthin + zeaxanthin)/(antheraxanthin + zeaxanthin + violaxanthin). C, Effect of nigericin and DTT on the kinetics of NPQ formation. Prior recording kinetics as described in Figure 2, plants were vacuum infiltrated with 50 μM nigericin (NGC) or 5 mM DTT. The curves for control leaves (infiltrated with water) were similar to those presented in Figure 2 and therefore are not shown here.
these data indicate that the taac plants are more susceptible than the wild type to high light, since the repair of PSII is malfunctioning in taac plants, while the photoprotection capacity does not differ between the two types of plants.

Leaves from plants exposed for 3 h to HL also have been studied in terms of chloroplast ultrastructure using electron microscopy (Fig. 6D). The dynamic structure of the grana can be dismantled and re-formed, during the processes known as destacking and restacking, on a timescale of minutes (for review, see Anderson et al., 2008). Notably, the mutant retained slightly, but significantly, higher grana than their respective ecotype plants (i.e. approximately 6 versus 5 appressed thylakoid lamellae per grumus on average). The granum length was also slightly, but significantly, longer in the mutant than in its respective ecotype (0.54 ± 0.15 and 0.51 ± 0.15 μm, respectively). When compared with the electron microscopy data obtained at GL conditions (Fig. 1C), it is obvious that HL treatment has induced destacking of grana and a decrease in granum length, but this process appeared to be partially inhibited in the mutant. The higher stacking in the mutant could be a protective mechanism against the effects of excess light and could also prevent access of proteases to the damaged D1 protein in PSII complexes unable to repair, as recently reported (Fristedt et al., 2009).

**Organization of PSII Complexes**

To explain the inability to degrade D1 in photo-inactivated PSII, we tested whether the deficiency of TAAC has an impact on the organization of PSII complexes in plants grown under GL and HL conditions. Thylakoids were isolated and solubilized mildly with detergent (dodecyl β-D-maltoside), and the various types of Chl protein complexes were separated by Blue-Native gel electrophoresis (BN-PAGE; Supplemental Fig. S8A). Western blotting with anti-D1 antibody identified four types of PSII subcomplexes: PSII-LHCII supercomplexes, PSII core dimers, PSII core monomers, and CP43-less monomers (Supplemental Fig. S8B). As revealed by quantification data presented in Table III, approximately 50% and 65% of the PSII complexes were found as monomers (sum of PSII core and CP43-less monomers) in wild-type and taac plants grown under GL conditions, respectively. Notably, the PSII supercomplexes were clearly less abundant in taac plants, indicating that PSII is already inhibited under GL conditions and requires repair. CP43-less PSII monomers represent the form that accumulates under conditions of intensive PSII repair, including D1 degradation (Rokka et al., 2005). Indeed, the mutant forms more CP43-less monomers with respect to the wild type, but the ratio to PSII core monomers is quite similar in the two types of plants (6:2 and 5:1, respectively). When grown under HL conditions, the PSII monomers dominated over the dimers in both types of plants, i.e. approximately 85% monomers were detected. Despite this, the wild-type plants accumulated the largest amounts of CP43-less monomers (20%) compared to the mutant (6%). The calculated ratio of 13:1 for PSII core monomers to CP43-less monomers in taac compared to 3:1 in the wild type indicates a poor dissociation of CP43 from the PSII monomer in taac plants during repair.
DISCUSSION

Arabidopsis contains an ATP/ADP carrier in the chloroplast thylakoid membrane, named TAAC. Its high expression levels under high light stress conditions (Thuswaldner et al., 2007), which primarily induce an inactivation of the PSII complex in the thylakoid membrane, pointed to a role of TAAC in the turnover of this complex. In this study, we employed a combination of biochemical, physiological, and electron microscopy approaches to investigate two taac mutant lines. Although the mutants were from two different collections and ecotypes, their phenotype was similar, emphasizing the specific effect of the mutation. We show that depletion of TAAC results in reduced plant growth. The mutants display wild-type levels of photosynthetic pigments, proteins, and activities. Therefore, the reduced growth must be a physiological consequence of TAAC depletion and its impact on the PSII repair cycle, more specifically impairment of CP43 dissociation from the complex, a step preceding the proteolytic degradation of the D1 protein. We also show that in the absence of TAAC, a higher trans-thylakoid electrochemical H+ gradient is used in the first minutes of illumination to induce transiently higher NPQ levels, which relaxes when reaching steady state levels.

The distinct response of PSII complexes to high light stress in the wild type and taac plants is likely to provide information about the physiological role of the TAAC protein by supplying nucleotides in the thylakoid lumen. The deficiency of TAAC increases the

susceptibility of PSII to photoinhibition (Figs. 3 and 6). The inhibition of D1 protein degradation results in the malfunctioning of the repair cycle. The site of malfunction was localized at the step when CP43 dissociates from damaged PSII, since a relatively low proportion of CP43-less monomers were detected in the mutant compared with the wild type, and most complexes were found as intact core monomers (Table III; Supplemental Fig. S8).

Interestingly, the phenotype of a T-DNA insertion line lacking the PsbO2 protein (psbo2) resembles taac with respect to PSII repair during HL stress. The psbo2 mutant displays smaller size and reduced HL stress tolerance, impaired D1 protein degradation, and predominance of the core monomer over the CP43-less monomer (Lundin et al., 2007b, 2008). This raises the question whether the poor dissociation of the CP43 subunit from the PSI core monomer observed in taac and psbo2 plants is due to a cross talk between TAAC and PsbO2 in performing ATP transport and GTPase-mediated signaling, resulting in efficient turnover of the D1 protein. The following lines of experimental evidence support this hypothesis. (1) D1 protein degradation following PSII photoactivation is a GTP-dependent process (Spetea et al., 1999). (2) PsbO is a GTPase and dissociates from PSI complex in a light- and GTP-dependent manner (Lundin et al., 2007a). PsbO is present in PSI core monomers but not in CP43-less monomers (Rokka et al., 2005), indicating that its dissociation precedes that of CP43. (3) Arabidopsis PsbO2 is a better GTPase than PsbO1. Its elimination leads to accumulation of PSI core monomers and impaired repair cycle (Lundin et al., 2007b, 2008). (4) TAAC depletion leads to a reduced thylakoid ATP transport and conversion to GTP in the lumen (Thuswaldner et al., 2007) as well as to accumulation of PSI core monomers and impaired repair cycle (this study). Interaction of TAAC with PSI proteins is not documented, and its function is most likely to supply nucleotides to the lumen for PsbO2-mediated signaling of PSI disassembly.

Generally, the short-term photosynthetic acclimation of plants to high light includes reversible phosphorylation of thylakoid membrane proteins and the dissipation of excess excitation energy as heat. Based on our results, it appears that the former is functioning optimally in taac mutants, whereas the latter is more efficiently activated compared to the wild type. The PSII proteins were found similarly phosphorylated in taac and the wild type in both dark- and light-adapted plants (Fig. 5B). A similar phosphorylation pattern was observed in the previously characterized psbo2 mutant (Lundin et al., 2007b). This would imply that the responsible protein kinases and /or phosphatases require neither luminal nucleotides supplied by TAAC nor GTPase-mediated signaling.

Regarding NPQ, the taac mutants were distinguishable from the respective wild-type ecotypes particularly in terms of rate and amplitude of the initial rapid phase of NPQ formation and also in terms of activation of violaxanthin de-epoxidase (Figs. 2 and 4; Supplemental Fig. S5D). Notably, psbo2 plants display similar NPQ induction and capacity as the wild type (Allahverdiyeva et al., 2009). This implies that the NPQ pattern observed in taac plants is not related to the impaired GTP-mediated PSII repair cycle during photoinhibition, but rather a physiological consequence of TAAC depletion.

Two relevant questions are whether and by which mechanism the deficiency of TAAC leads to a transient acidification of the lumen in the first minutes of illumination. In vivo measurements in wild-type and taac plants did not reveal significant differences in the electrochemical H+ gradient (A. Kanazawa, D.M. Kramer, and C. Spetea, unpublished data). The cellular homeostasis, similar to that of the wild type, is most likely reached in the mutant in order to maintain steady and balanced electrochemical gradient across the thylakoid membrane. Nevertheless, there are several lines of evidence to support the establishment of a transiently higher thylakoid H+ gradient in the mutant: (1) an enhanced stimulatory effect of NH4Cl on the rate of oxygen evolution from isolated thylakoids; (2) faster and higher amplitude of the initial rapid phase of NPQ formation in dark-adapted leaves, but not in preilluminated leaves (this pattern is preserved in DTT-treated, but not in nigericin-treated, leaves); (3) a higher de-epoxidation ratio and, thus, a more active violaxanthin de-epoxidase. The steady-state NPQ levels are indistinguishable between the wild type and mutants and are lowered drastically by nigericin and to a lower extent by treatment with DTT. Therefore, we cannot exclude that an important fraction of the observed NPQ is zeaxanthin independent. This will support previous and recent observations about zeaxanthin-independent NPQ mechanisms (Finazzi et al., 2004; Li et al., 2009; Lambrev et al., 2010). Thus, the transient accumulation of higher electrochemical H+ gradient in the mutants more efficiently activates photoprotective xanthophyll cycle-dependent and -independent mechanisms compared to the wild type.

We do not understand at present stage the mechanism by which absence of TAAC leads to the above discussed effects on H+ gradient and photoprotection. An attractive possibility would be that trans-thylakoid adenine nucleotide exchange by TAAC is electrogenic (ATP3− / ADP2−), as demonstrated for the mitochondrial AAC-catalyzed transport (Gropp et al., 1999). Although AAC and TAAC share a similar structure and antiport mechanism (Thuswaldner et al., 2007), the electrogenic properties of TAAC activity dissipating a fraction of the H+ gradient in the wild-type plants, while accumulating it in the taac mutants, remain to be investigated.

The results presented and discussed here support the previously proposed significant role of the thylakoid lumen in metabolism and cellular signaling. The thylakoid lumen is a multifunctional cellular compartment, as based on the large variety of proteins iden-
Materials and Methods

Plant Material and Growth Conditions

The taac mutant is a T-DNA insertion knockout Arabidopsis (Arabidopsis thaliana) mutant for the TAAC gene (At5g01500; FLAG_443D03, Ws ecotype) obtained from PublicLines at Institut National de la Recherche Agronomique (http://dbsgap versailles.inra.fr/publiclines/). PCR analysis was performed to confirm the homozygosity of the mutant, whereas the absence of the TAAC protein was verified by western blotting, as described (Thuswaldner et al., 2007). The Southern-blot analysis of HindIII-digested mutant performed with a T-DNA-specific probe demonstrated that the FLAG line contained only one T-DNA insert (Supplemental Fig. S1). The details of the Southern blotting are given in Supplemental Materials and Methods S1.

Arabidopsis seeds for the SAIL_209_A12 T-DNA insertion line for the TAAC gene (Columbia ecotype; Supplemental Fig. S2A) were produced by SAIL (StiekElvier et al., 2001) and ordered at the Salk SIGnAL T-DNA express Arabidopsis Gene mapping tool (http://www.signal.salk.edu/cgi-bin/tDNAexpress). PCR and RT-PCR analyses of this mutant are given in Supplemental Materials and Methods S1. Although of different ecotypes, the SAIL_209_A12 mutant showed visible phenotypes identical with FLAG_443D03, chosen for detailed physiological and biochemical characterization. Characterization of SAIL_209_A12 is presented in Supplemental Table S1 and Supplemental Figure S4.

The two mutants and wild-type Arabidopsis of respective ecotype were grown hydroponically at an irradiance of 120 μmol photons m⁻² s⁻¹ (GL) at 22°C with 8-h-light/16-h-dark cycles and relative humidity 70% for 42 d unless otherwise indicated. For HL stress experiments, 28-d-old GL plants were grown at an irradiance of 950 μmol photons m⁻² s⁻¹ (HL) for an additional 28 d. For pigment analysis, plants were grown on soil under GL conditions for 15 to 17 d before use. For analysis of PSI subcomplexes, plants were grown on soil for 21 d under GL conditions and then grown for additional 14 d under either GL or HL conditions.

Chlorophyll Fluorescence, Oxygen Evolution, P₇₀₀ Oxidoreduction, and CO₂ Fixation

Chl fluorescence at room temperature was measured using a pulsed-amplitude fluorometer either dual PAM-100 (for the data presented in Table II and Supplemental Fig. 5S) or model PAM-210 (Walz; for the data presented in Figs. 2, 3, and 6 and Supplemental Fig. S3). The maximum quantum yield of PSI photochemistry (Fv/Fm) was determined as a ratio of variable fluorescence (Fv) to maximal fluorescence (Fm) measured from attached leaves dark adapted for 15 min.

Fast kinetics of Chl fluorescence induction were recorded, and the obtained O-J-I-P transient was analyzed according to the JIP-test (Strasser et al., 1996). Using the fluorescence parameters, the energy fluxes per RC were calculated. For details and equations, see Supplemental Materials and Methods S1. All the measurements were performed on attached leaves dark adapted for 15 min.

During HL growth, the maximum quantum yield of PSI photochemistry was determined as Chl fluorescence (Fv/Fm) in leaves harvested after the 8-h light period followed by 15 min of dark adaptation. For determination of NPQ, slow kinetics of Chl fluorescence induction were recorded in leaves detached from 16 h dark-adapted plants, exposed for 20 min to PAR of 300, 600, and 1430 μmol photons m⁻² s⁻¹. Where indicated, Chl fluorescence was recorded in 3 h HL-treated leaves by an open gas portable photosynthesis system (LI-6400; LI-COR) as described in Supplemental Materials and Methods S1.

Electron Microscopy

The plants used for ultrastructural investigations were 28 d old. The leaves were directly fixed at least 3 h after the start of the light phase and prepared for electron microscopy as described by Abdelkader et al. (2007). The ultrastructural (70 nm) sections of the leaf CSs were investigated by a Hitachi 7100 transmission electron microscope at 75-kV accelerating voltage. From all samples at least 35 grana were measured (antheraxanthin + zeaxanthin)/(antheraxanthin + zeaxanthin + violaxanthin). The granum height (number of appressed thylakoid lamellae) and length were determined and measured at the middle of the granum.

Pigment Analysis

Chl content of whole leaves was determined by extraction in 96% ethanol and spectrophotometry according to Lichtenthaler and Wellburn (1983). For determination of the xanthophyll cycle activity, the leaves were illuminated for 20 min with PAR of various intensities ranging between 53 and 1,952 μmol photons m⁻² s⁻¹. Because long and intense illumination triggers pigment photodestruction, the time of illumination was reduced to 10 min for PAR intensity higher than 1,000 μmol m⁻² s⁻¹, as recommended by Niyogi et al. (1998). When the illumination period was completed, Chl and carotenoids were extracted from detached leaves (Schoefs, 2002) and analyzed by HPLC (Darko et al., 2000). Details are provided in Supplemental Materials and Methods S1. The xanthophyll cycle or de-epoxidation ratio was measured as (antheraxanthin + zeaxanthin)/(antheraxanthin + zeaxanthin + violaxanthin).

Thylakoid Preparation

Thylakoid membranes were isolated from 16-h dark-adapted plants and purified as described (Nörlin et al., 1999). In some experiments aimed at studying the steady-state level of phosphorylation of PSI proteins, thylakoid membranes were isolated in the presence of 10 mM NaF (a general inhibitor of protein phosphatases) from plants that were dark adapted and exposed for 3 h to GL or HL. Chl concentration was determined spectrophotometrically in 80% acetone according to Porra et al. (1989).

Short-Term Light Treatment

In experiments aimed to study the effect of inhibition of chloroplast protein synthesis, detached leaves were treated with 2 mM lincomycin in darkness overnight. The leaves together with the media were then transferred to petri dishes and exposed to GL or HL for 1 and 3 h at 22°C. Chl fluorescence was measured in control and lincomycin-treated leaves after 5 min of dark adaptation. For quantification of D1 protein levels, the leaves were frozen in liquid nitrogen and stored at −80°C until isolation of thylakoid membranes. Where indicated, Chl fluorescence was recorded in 3 h HL-treated leaves during a subsequent period of recovery in darkness.

SDS-PAGE, BN-PAGE, and Western Blotting

Thylakoid proteins were separated by SDS-PAGE using 14% (w/v) acrylamide gels with 6 wt urea. Following electrophoresis and electroblotting, various photosynthetic proteins were immunodetected using specific antibodies and the ECL-Plus detection system (GE Healthcare). Antibodies were raised in rabbit against PsAΑ/B, CP43, D2, PSbO, and PsbP proteins from spinach (Spinacia oleracea). Antibodies against the CFI β-subunit of ATP-synthase, Lhcb1, Lhcb2, and PsbS proteins were purchased from Agrisera.
Where indicated, rabbit anti-phosphotheanine antibodies from Cell Signaling were used.

For determination of PSII subcomplex distribution, thylakoid membranes were isolated and solubilized as described (Lundin et al., 2008). The Chl protein complexes were separated by BN-PAGE, and the PSII complexes immunodetected with the anti-D1 antibody.

Statistical Analysis

The mean and so were calculated for each data set, where appropriate. Standard error bars were plotted except where smaller than the symbol size. Where appropriate, the Student’s t test was used to identify the difference between the wild type and the mutant.

Supplemental Data

The following materials are available in the online version of this article.

Supplemental Figure S1. Southern blot of the EcorI-digested FLAG_443D03 taac mutant DNA probed with a radiolabeled T-DNA fragment.

Supplemental Figure S2. Screening for homozygous Arabidopsis SAIL_209_A12 taac mutant.

Supplemental Figure S3. Characterization of the SAIL_209_A12 taac knockout mutant.

Supplemental Figure S4. CO₂ fixation of the taac mutant and wild-type Arabidopsis Ws ecotype.

Supplemental Figure S5. Fast fluorescence kinetics of taac mutant and wild-type Arabidopsis Ws ecotype.

Supplemental Figure S6. A highly simplified model presenting the energy fluxes per RC in photosystem II.

Supplemental Figure S7. Steady-state levels of nonphotochemical quenching in high-light-stressed leaves.

Supplemental Figure S8. Analysis by Blue Native gel electrophoresis (BN-PAGE) of protein complexes from wild-type and taac plants.
