Glandular trichomes play important roles in protecting plants from biotic attack by producing defensive compounds. We investigated the metabolic profiles and transcriptomes to characterize the differences between different glandular trichome types in several domesticated and wild Solanum species: Solanum lycopersicum (glandular trichome types 1, 6, and 7), Solanum habrochaites (types 1, 4, and 6), Solanum pennellii (types 4 and 6), Solanum arcanum (type 6), and Solanum pimpinellifolium (type 6). Substantial chemical differences in and between Solanum species and glandular trichome types are likely determined by the regulation of metabolism at several levels. Comparison of S. habrochaites type 1 and 4 glandular trichomes revealed few differences in chemical content or transcript abundance, leading to the conclusion that these two glandular trichome types are the same and differ perhaps only in stalk length. The observation that all of the other species examined here contain either type 1 or 4 trichomes (not both) supports the conclusion that these two trichome types are the same. Most differences in metabolites between type 1 and 4 glands on the one hand and type 6 glands on the other hand are quantitative but not qualitative. Several glandular trichome types express genes associated with photosynthesis and carbon fixation, indicating that some carbon destined for specialized metabolism is likely fixed within the trichome secretory cells. Finally, Solanum type 7 glandular trichomes do not appear to be involved in the biosynthesis and storage of specialized metabolites and thus likely serve another unknown function, perhaps as the site of the synthesis of protease inhibitors.

Trichomes are epidermal structures widely conserved across the plant kingdom (Kim and Mahlberg, 1991; Wagner, 1991; Alonso et al., 1992; Yu et al., 1992; Kolb and Muller, 2003; Valkama et al., 2003; Giuliani and Bini, 2008). These structures perform important biological functions, such as discouraging herbivory, attracting pollinators, and maintaining a boundary layer (Nihoul, 1993; Van Dam and Hare, 1998; Kennedy, 2003; Moyano et al., 2003; Simmons and Gurr, 2005; Liu et al., 2006; Horgan et al., 2007; Gonzalez et al., 2008; Romero et al., 2008; Nonomura et al., 2009; Kang et al., 2010). Many of these functions are the result of the specialized nature of glandular trichomes (glands) as sites for the synthesis and storage of biologically active specialized metabolites (Alonso et al., 1992; Antonious, 2001; Iijima et al., 2004; Siebert, 2004; Deschamps et al., 2006; Nagel et al., 2008; Wang et al., 2008; Biswas et al., 2009; Sallaud et al., 2009). Comparisons between domesticated crop species and their wild progenitors have revealed that many of the more potent, glandular trichome-derived specialized metabolites have been lost during domestication (Rodriguez et al., 1993; Oghiakhe, 1997; Medeiros and Tingey, 2006; Zhang et al., 2008; Besser et al., 2009). The loss of these important compounds has led to an increased susceptibility of domesticated crops to pathogen and herbivore attack compared with their wild counterparts (Rodriguez et al., 1993; Puterka et al., 2003; Chao et al., 2006; Nonomura et al., 2009), and reintroduction of such compounds into crop species may prove to be an effective way to combat crop loss due to insects and disease.

The genus Solanum possesses two general categories of trichomes: nonglandular and glandular. The nonglandular trichomes are generally linear trichomes that lack secretory/storage cells at their tips (Schwab et al., 2000) and thus are not of interest for this investigation. The glandular trichomes of Solanum,
on the other hand, first described by Luckwill (1943) and later reviewed extensively by Simmons and Gurr (2005), have been described as consisting of four distinct classes (types 1, 4, 6, and 7). The density of these glandular trichome types can vary according to species, cultivar, tissue, and environmental conditions (Luckwill, 1943; Wilkens et al., 1996; Economou et al., 2006; Maluf et al., 2007; Kang et al., 2010). The glandular trichome types differ according to the size and length of the supporting stalk as well as the number of secretory cells making up the glandular tip. In addition, other differences, such as in chemical content, have been proposed between most of these four types of glandular trichomes. Indeed, type 6 glandular trichomes are known to be the major site of terpenoid production in cultivated tomato (*Solanum lycopersicum*; Schilmiller et al., 2009; Kang et al., 2010).

To determine the biological roles and chemical contents of individual glandular trichome types in various *Solanum* species, we have taken a comparative functional genomics approach with particular emphasis on analysis of the glandular trichome secretory cell transcriptome and metabolic profile. This analysis has allowed us to address several important questions. What are the roles of the different glandular trichome types? Do some plants make more than one type of glandular trichome? What specialized functions do different glandular trichome types possess? And where do specific specialized metabolic processes occur (e.g. terpenoid versus acyl sugar production)?

**RESULTS AND DISCUSSION**

**Isolation and Analysis of Different Trichome Types in Different Solanum Species**

Accessions from five *Solanum* species were chosen for analysis: *Solanum habrochaites* (LA1777), *Solanum pimpinellifolium* (LA1589), *Solanum pennellii* (LA0716), *Solanum arcanum* (= *Solanum peruvianum*; LA1708), and *S. lycopersicum* (= *Lycopersicon esculentum*; M82). Within these species, several types of glandular trichomes are present and vary in abundance (Fig. 1; Table I). Of specific interest were secretory cells of type 1, 4, 6, and 7 glandular trichomes, which remain largely uncharacterized at the individual level across *Solanum* species. A recent report (Slocombe et al., 2008) describes the analysis of total trichome preparations from *S. pennellii*, which formed a reference point for our analysis, but did not analyze individual trichome type secretory cells.

The trichomes referred to as types 1 and 4 glandular trichomes, as shown in Figure 1, A, B, I, and J, appear to be physically similar to nonglandular hairy trichomes but terminate with globe- or oblong-shaped one- to two-cell storage/secretion units that may or may not be covered by a waxy cuticle. One hypothesis explaining the physical similarities between these two glandular trichome types is that type 1 and type 4 trichomes represent different stages of development (Kang et al., 2010). However, both are present on very young leaves as well as on fully mature leaves. Despite their apparent physical differences, both types accumulate small droplets on their tips that contain sticky acyl sugar compounds (Rodriguez et al., 1993; Alba et al., 2009; Nonomura et al., 2009). The accumulation of such compounds is pronounced in *S. pennellii* and *S. habrochaites*, which have abundant type 4 trichomes (Weston et al., 1989; Snyder et al., 1998), resulting in a sticky residue when leaves of these species are handled. The opposite is true for *S. arcanum* and *S. lycopersicum*, which possess type 1 trichomes but lack the profuse secreting nature of *S. habrochaites* and *S. pennellii* type 1 or 4 trichomes.

The other dominant glandular trichome in *Solanum* species is the type 6 gland, shown in Figure 1, F, K, and L. Composed of four disc cells at the end of a two-celled stalk, these glands are found on all species used in this study but are present in low abundance on *S.
pennellii leaves and stems. Unlike the secreting type 1 and 4 glands of *S. habrochaites* and *S. pennellii*, type 6 glands appear to be specialized to produce metabolites and then store them under a waxy cuticle, as has been described for other “peltate” glandular trichomes found in mint (*Mentha × piperita*), basil (*Ocimum basilicum*), and other species (Croteau, 1991; Turner et al., 2000; Gang et al., 2001; Deschamps et al., 2006; Gunning et al., 2007). In *Solanum* type 6 glands, the area under the cuticle is filled completely and ready to release its contents given either the correct environmental conditions or physical contact (Lin et al., 1987; Maluf et al., 2007; Ben-Israel et al., 2009).

The final glandular trichome type of interest is the type 7 glandular trichome depicted in Figure 1M. Of all glandular trichomes analyzed, this gland is both of low abundance (Simmons et al., 2003) and the least characterized, due not only to its scarcity but also to its general physical properties. Located in close proximity to the epidermis, this glandular trichome consists of a small multicellular glandular head situated on a short, single-celled stalk, making it very difficult to isolate. Like the type 6 gland, type 7 glandular trichomes also possess a waxy cuticle that has been observed in our studies to be removable with harsh abrasive treatment. The exact content of the mixture under the waxy cuticle of type 7 glands remains unclear and is discussed below.

To collect enough glandular secretory cells for metabolomic and transcriptomic analyses, a variety of methods were employed. To collect the type 1 and 4 glands from the various *Solanum* species, microscissors were used to clip the glandular heads off of the stalks. This leads to very pure fractions of just the glandular head cells. Two alternative approaches were used to isolate the type 6 gland heads. The first approach involved directly “picking” type 6 glandular trichome heads using stretched glass pipettes (Schiml et al., 2009; Kang et al., 2010), while the second approach utilized glass beads in buffer to abrasively remove trichomes from the leaf surface (Gang et al., 2001; Fridman et al., 2005). Fractions enriched in type 7 glandular trichome secretory cells were obtained using the bead-beater procedure. Methods employing liquid N₂ or dry ice (Yerger et al., 1992) did not work well for our purposes, as these preclude the ability to separate different types of trichomes from each other and lead to trichome fractions that consist mostly of the nonglandular stalks. The methods used in this investigation allowed us to obtain very pure preparations consisting almost exclusively of the secretory cells of interest. Secretory cells collected for transcriptome profiling were flash frozen in liquid nitrogen, whereas cells destined for metabolite profiling were immediately suspended in ice-cold solvent before being further processed (see “Materials and Methods”).

**Gross Comparisons of Trichome Metabolite Profiles in *Solanum* Species**

Metabolite profiles obtained for the 10 species/type entries marked as abundant or sparse in Table I were produced using a liquid chromatography (LC)-time of flight-mass spectrometry (MS)-based method and revealed that the majority (79%) of the detected compounds were unknowns (Supplemental Table S1). However, 119 known compounds were detected and their relative quantities determined between gland types and between species. It was impossible to determine absolute levels for these compounds in our samples because of differences in ionization efficiencies and potential ion suppression due to variable matrix effects. Moreover, potential intrametabolite contamination from the type 1/4 trichome exudates for the type 6 trichome samples may exist, especially for the type 6 samples from *S. habrochaites* and *S. pennellii*. Thus, it was also not possible to determine accurate differences in abundance for compound/compound comparisons. Nevertheless, trends in compound class abundance between trichome types and between species, based on relative quantification values, were determined. The box plot in Figure 2 shows the distribution of normalized peak areas for aggregate metabolite classes for known compounds detected in the various *Solanum* species and trichome types, providing a general concept of the prevalence of various compound classes in different glandular trichome extracts. The results presented in this figure must be evaluated with caution, however, in light of the issues of nonuniform ionization efficiencies and...
potential ion suppression and matrix effects mentioned above. Nevertheless, these results suggest interesting trends regarding metabolite production in these trichomes, where metabolite modules appear to be present and imply mechanisms involved in controlling the production of specific compounds and groups of compounds (Fig. 3; Supplemental Figs. S1 and S2; Supplemental Table S2; Xie et al., 2009).

The normalized data used to produce Figure 3 revealed that the known metabolites observed in *Solanum* trichomes are differentially distributed between trichome types and species and that this variation is generally more evident between species than within. For example, *S. habrochaites* glands contain the most diverse set of known fatty acids, sesquiterpenes, and acyl sucroses of all species and glandular trichome types (Supplemental Table S2; Supplemental Fig. S2, clusters 2A–2Y). Likewise, *S. pennellii* glands were dominated by acyl glucoses (Supplemental Fig. S2, clusters 1A–1H) compared with other species and gland types. It is also clear from Figure 2 that cultivated tomato (M82) lacks the chemical diversity of many of the wild species and is more similar to *S. arcanum* and *S. pimpinellifolium* than to *S. pennellii* and *S. habrochaites*, a conclusion further supported by the data shown in Figures 2 to 4 and Supplemental Figures S2 and S3. Figure 4, displaying results from additional multivariate statistical analyses (principal component analysis [PCA] and partial least squares-discriminant analysis [PLS-DA]) of the metabolite data set with individual samples from all species viewed separately instead of by analyzing means of replicates, clearly shows that *S. lycopersicum*, *S. arcanum*, and *S. pimpinellifolium* are closely related metabolically, regardless of trichome type. The similar metabolite profiles and morphologies of *S. lycopersicum*, *S. arcanum*, and *S. pimpinellifolium* is consistent with the close phylogenetic relationship among these species (Peralta and Spooner, 2001). These profiles are also illustrative of *S. lycopersicum*’s limited ability to produce and/or store the metabolites measured in our analysis within its glandular trichomes, although it does produce significant levels of a handful of monoterpenoids and sesquiterpenoids (Kang et al., 2010). This reduced chemical diversity relative to wild species may help to explain observations that the resistance of domesticated tomato cultivars to certain arthropod herbivores is less than that of many wild tomato species (Kumar et al., 1995; Pico et al., 1998; Martins Santana et al., 2001).

What was quite surprising was that greater differences were observed in overall metabolite profiles for the same glandular trichome type across species than were observed for comparisons of different gland types within the same species. For example, PLS-DA (Fig. 4C) and PCA (Fig. 4, C–F) analyses of metabolite data obtained for *S. habrochaites* (accession LA1777), the only accession that had readily isolatable glandular trichomes for all types (1, 4, 6, and 7), demonstrated that glandular trichome types 1 and 4 were indistinguishable from each other. Hierarchical cluster analysis (Supplemental Fig. S3A) also failed to separate type 1 and 4 trichomes based on overall or aggregate metabolite profiles, regardless of the method used for data normalization. The normalization used for the data presented above was log_{2}-transformed data. Other normalization methods, such as autoscaling, pareto scaling, or range scaling, gave even poorer resolving power, where type 6 trichomes were also not readily differentiated from the type 1 or 4 trichomes.
Interestingly, glandular trichomes from stems could be differentiated from glandular trichomes isolated from leaf surfaces (Fig. 4, D and F), depending on which principal components were considered, suggesting that significantly different metabolite profiles may exist for stems versus leaves. Such results only present an aggregate picture of a greater metabolomic content, however, and do not allow for closer inspection of how specific compounds that might be involved in specific plant defenses may be produced or regulated.

When specific classes of compounds were compared, instead of gross aggregate profiles, a few notable differences were observed among the different trichome types within species. For example, *S. lycopersicum* type 1 and 6 glandular trichomes exhibited markedly dissimilar profiles for certain subsets of metabolites. Whereas the levels of acyl glucoses in both types of *S. lycopersicum* glands were very low (although they were more abundant in the type 6 glands than in type 1), type 1 extracts from the same species were dominated by acyl sucroses (Supplemental Fig. S2, clusters 1A, 1E, 1G, 1H, 2I, 2O, 2T, and 2Y), but such compounds did not appear to be present in type 6 glands from this particular species. In addition, *S. habrochaites* type 1 and 4 trichomes had approximately 5-fold higher levels of methylated myricetin.
We observed great variability in relative amounts of acyl sugars between different preparations of the same gland type, especially for *S. pennellii* type 6 and 4 gland preparations. And, despite the possibility of variable matrix effects, the differences between preparations of a single gland type were very large compared with the likely variation resulting from matrix effects. Therefore, we are not convinced that further chemical analyses (even if acyl sugar standards were available) would enhance our understanding of the differences between gland chemistries.

Trichome Transcriptomes in *Solanum* Species

The transcriptomes of the secretory cells of various glandular trichome types from the different species were analyzed using a transcriptome sequencing approach, with six and eight libraries sequenced using Sanger and 454 approaches, respectively (Table I), resulting in $1.4 \times 10^6$ ESTs. The ESTs for the five species were separately assembled with PAVE (Soderlund et al., 2009) and annotated with UniProt (UniProt Consortium, 2010) and Rstat (Stekel et al., 2000). The ESTs from all trichome/species libraries were also assembled together, resulting in 32,261 contigs and 49,958 singletons. Annotation of these trichome/species contigs and singletons resulted in 80% of sequences being assigned a UniProt identifier, of which 33,092 had UniProt identifiers from plants as a top match. The resulting transcriptomic data can be viewed and analyzed at http://www.agcol.arizona.edu/pave/solanum/. This approach contrasts to what has been reported before for *S. pennellii*, where total trichomes, including stalks, were aggregated (trichome types were not distinguishable) analyzed for gene expression level by hybridization to the *S. lycopersicum* TOM2 microarray, an array containing sequences from different *Solanum* species than what was used in the hybridization analysis (Slocombe et al., 2008). Such cross-species microarray experiments, while capable of differentiating rough relative expression levels between tissues within the same species for many (but not all) genes in the target species, are not capable of providing absolute expression levels or of being useful

Figure 4. PCA and PLS-DA of metabolite profiling data for comparison of trichome types of all species evaluated in this investigation (A and B) and of all trichome types from *S. habrochaites* (LA1777; C–F).
when comparing expression for any particular gene between species (Chain et al., 2008; Gilad et al., 2009). Thus, it is unfortunately practically impossible to draw comparisons between our approach and what has been previously published with regard to observed levels of expression for any particular gene, as our approach was fundamentally different from what has been described before.

**Comparison of Type 6 Glandular Trichomes between Solanum Species**

Analysis of metabolites from type 6 glandular trichomes across all five species resulted in the same trends discussed in the gross comparisons of metabolites across all species and glandular trichome types. Compared with the other species, *S. habrochaites* and *S. pennellii* type 6 glands have more in common with one another than they do with *S. lycopersicum, S. arcuncium, and S. pimpinellifolium* (Figs. 2 and 3). Moreover, the *S. habrochaites* type 6 extracts also contain the most diverse sets of metabolites (which are specific to *S. habrochaites* type 6) compared with other species (Supplemental Fig. S2), being dominated by acyl sucroses, terpenoids, and fatty acids (Supplemental Fig. S2). *S. pennellii* type 6 glands possess the second most diverse complement of specialized metabolites specific to one species, containing the most diverse set of acyl glucose in our comparisons (Supplemental Fig. S2). In contrast, type 6 gland extracts from *S. lycopersicum*, *S. pimpinellifolium*, and *S. arcuncium* are very similar to each other (Supplemental Fig. S2), and both the diversity and quantity of metabolites in these three species are extremely limited. The unique type 6 glandular trichome metabolite profiles may play important roles in conferring to wild *Solanum* species resistance to disease and insect herbivory (Kumar et al., 1995; Pico et al., 1998; Martins Santana et al., 2001).

Gross analysis of *Solanum* type 6 transcriptomes revealed that transcripts for enzymes and proteins associated with photosynthesis light reactions, photosynthetic carbon fixation, glycolysis/gluconeogenesis, starch and Suc metabolism, and the citrate cycle were prevalent, in addition to many other downstream primary metabolic processes (Supplemental Table S3; Supplemental Figs. S4–S7; a reference iPath map can be accessed at http://pathways.embl.de/default_map.html for comparison), suggesting that *Solanum* type 6 glandular trichomes may be able to produce specialized compounds de novo, perhaps without the requirement for transport and uptake of source carbon from stalk cells. This contrasts somewhat with the report that in *S. pennellii* total trichomes, the expression level for photosynthesis-related genes was greatly reduced (Slocombe et al., 2008), based on hybridization to a nonspecies microarray platform (the TOM2 Affy array is based on a limited set of genes from a specific *S. lycopersicum* cultivar and not on *S. pennellii*). However, the trichome stalk cells provided the vast majority of the cell mass and presumably RNAs in that study (Fig. 2, G and H, in Slocombe et al., 2008). In our study, we analyzed only the secretory cells for the majority of the trichome types analyzed, or only small portions of the stalks were included when microscissors were used to clip off the trichome heads at their connection to the stalk. This may have led to our ability to detect significant levels of expression of some photosynthesis-related genes, whereas the other report did not observe this.

Developing oil seed embryos from some species do not necessarily rely solely on imported Suc and the oxidative pentose phosphate pathway but rather also utilize an endogenous photosynthetic apparatus to provide both carbon skeletons and reducing power for oil (triglyceride) synthesis (Goffman et al., 2004; Alonso et al., 2007; Junker et al., 2007; Allen et al., 2009). Similarly, Wang et al. (2009) recently claimed that photosynthesis genes are expressed at very high levels in the glandular trichomes of *Artemisia annua*, with chlorophyll *a/b*-binding protein and ribulose bisphosphate carboxylase small subunit being among the top 10 most highly expressed transcripts in the trichomes of that species, and that in situ carbon fixation may be involved in the production of artemisinin in these trichome secretory cells. However, close inspection of figure 5 (isolation of glandular trichomes) from that report reveals significant contamination by green mesophyll cells in the final glandular trichome preparation used for 454 transcriptome analysis. The glandular trichomes shown in that figure appear to be colorless. Thus, it is not clear whether or not de novo carbon fixation in the secretory cells is indeed involved in the production of artemisinin, and the transcript levels observed may be due to expression not only in the trichome but also in underlying mesophyll cells that contaminated the trichome preparations. Indeed, species such as *Glycine max*, *Mentha* species, and basil possess glandular trichomes with plastids that lack developed thylakoid membrane systems and any apparent ability to perform photosynthesis (Franceschi and Giaquinta, 1983; Croteau, 1991; Gershenzon et al., 1992; McCaskill et al., 1992; McCaskill and Croteau, 1995; Lange et al., 2000; Turner et al., 2000; Gang et al., 2001; Turner and Croteau, 2004; Rios-Estepa et al., 2008; Xie et al., 2008). In these species, nonphotosynthetic plastids appear to be heavily involved in specialized metabolite synthesis. The glandular trichomes of *A. annua* appear to be of this type.

In contrast, work on tobacco (*Nicotiana tabacum*) glandular trichomes clearly suggested that some glandular trichomes of the Solanaceae have the ability to fix carbon and synthesize metabolites from sugar produced directly in the trichomes, although carbon imported into the trichome may also be involved (Keene and Wagner, 1985; Kandra and Wagner, 1988; Nielsen et al., 1991). The type 6 trichomes from *S. lycopersicum, S. arcuncium, S. pimpinellifolium*, and *S. habrochaites* used for 454 sequencing in this analysis were isolated using the glass-bead-shaking method.
However, the type 1/4 trichomes from all species and type 6 trichomes from S. pennellii used for both metabolite analysis and sequencing in this project were hand picked (Supplemental Fig. S20), leading to analysis of only the secretory cells and perhaps part of a stalk cell for those collected by the microscissors technique but no possible contamination by underlying mesophyll or other cell types. It must be noted that such photosynthesis-related genes were not among the most highly expressed in our analysis, as can be seen in Supplemental Tables S14 to S19, where many of them are listed. Therefore, the identification of transcripts for photosynthesis genes in the trichomes suggests the possibility that the secretory cells of Solanum species may possess the ability to have at least a rudimentary capacity for photosynthesis that may contribute to secreted metabolite synthesis. Thus, the role of imported versus de novo-synthesized sugars in glandular trichome secretory cell metabolism remains an area of intense interest.

Also observed in type 6 glands from all species, with the exception of S. pennellii, were transcripts representing the phenylpropanoid and flavonoid pathways. The lack of representation of the phenylpropanoid and flavonoid pathways in the transcriptome of S. pennellii type 6 glandular trichomes was likely the result of inadequate sampling of the transcriptome during sequencing (Supplemental Tables S4 and S5), as these trichomes were difficult to obtain due to the high densities of type 1/4 glands that obscured access, with the resulting production of only a small 454 library.

In further efforts to make quantitative comparisons between type 6 Solanum trichomes from these species, we utilized the methodology of Stekel et al. (2000) to identify differentially significantly expressed ESTs (Supplemental Tables S6 and S7) using summaries of three different annotations that were assigned as described in “Materials and Methods”: UniProt identification (UPID), Enzyme Commission (EC), and Gene Ontology. Supplemental Tables S6 and S7 provide interspecies and intraspecies comparisons for UniProt and EC, showing the normalized counts for up-regulated genes for each of the two species compared. The elements of the metabolic network present in Solanum type 6 trichome secretory cells are listed in Supplemental Table S3 and are pictorially reconstructed using the iPATH software (Letunic et al., 2008; Supplemental Figs. S4–S8). To ensure legitimate comparisons between library data sets, we took a conservative approach and only used library comparisons that were of similar size, collection method, sequencing technologies, and within the same sequence assembly (Supplemental Tables S4–S7). Thus, the type 6 gland comparisons that are listed in Supplemental Tables S6 and S7 excluded the S. arcanum and S. pennellii type 6 data sets. The three type 6 transcript comparisons that were performed reflect the metabolism profiles observed in the gross metabolite comparisons described above; this is shown in Supplemental Tables S8 to S15, which list overrepresented and underrepresented biological processes by Gene Ontology terms in each of the species. Interestingly, terpenoid-rich S. habrochaites appears to preferentially (compared with either S. pimpinellifolium or S. lycopersicum; Supplemental Table S14) express enzymes important for regulating flux into the terpenoid/isoprenoid pathway: 1-deoxy-D-xylulose 5-phosphate synthase 2 (annotated as Q6HlP4_SOLHA), 4-hydroxy-3-methylbut-2-enyl diphosphate reductase (annotated as Q2XBT5_SOLTU, LYTB-like protein), and Z,Z-farnesyl pyrophosphate synthase (annotated as B8XAA0_SOLHA). Also, S. habrochaites type 6 trichomes exhibit enriched expression of contig EC annotations implicated in processes associated with acyl sugar biosynthesis, including an acyl desaturase (EC 1.14.19.2) and an isopropylmalate synthase (EC 2.3.3.13; Supplemental Table S15; Slocombe et al., 2008). In contrast, it was not clear from this analysis why S. habrochaites type 6 glands contain limited quantities of Glc-derived acyl sugars compared with acyl sucroses, as ESTs for enzymes such as Suc synthase or gluconeogenesis pathway members were found in relatively equal abundance across species (Supplemental Tables S14 and S15). The mechanism responsible for regulating the production of these compounds remains unidentified, but based on our experiments, it is not likely to involve direct control by modulation of transcript levels.

In addition to the observations described above (i.e. that the specialized metabolites stored within the type 6 glandular trichome can be derived from imported, leaf-produced Suc or from carbon fixed within the trichome itself), the data also suggest that transcripts for general metabolic pathways that were detected were expressed at similar levels across species (Supplemental Tables S14 and S15). Additionally, it was evident that differences in type 6 gland biochemistry are likely due to differential up-regulation of select segments or branches of a pathway, not the whole pathway, as is suggested by Supplemental Figures S9 to S14. The differential regulation of select enzymes within type 6 glands is consistent with the biochemistries outlined in Figure 3, Supplemental Table S2, and Supplemental Figure S4, specifically with S. habrochaites compared with either S. lycopersicum or S. pimpinellifolium. It also appears that some differences in metabolite profiles between the species are most likely regulated at both the transcriptional and genomic levels. Unique EC annotations for the “same” enzyme between different species suggested that not only differences in expression levels for gene family members but also alterations in sequence leading to potentially differential activity may produce altered pathway functions.

A final determination was that type 6 glands also express genes not directly contributing to specialized metabolism. S. lycopersicum is the best example, and genes encoding enzymes and other proteins such as lipoxygenase, pathogenesis-related protein isoform b1, Arg decarboxylase, superoxide dismutase, various heat shock-related proteins, and of course polyubiqui-
Comparison of Type 1 and 4 Trichomes

Comparisons across all species for the physically similar type 1 and type 4 trichomes revealed that there are substantial differences between species for these glandular trichome types. Again the *S. pennellii* and *S. habrochaites* type 1/4 glands contained the most diverse sets of acyl sugars, phenylpropanoids, terpenoids, and alkaloids compared with other species (Fig. 2; Supplemental Fig. S2). For instance, *S. pennellii* type 4 glands, despite the presence of a few acyl sugars (Supplemental Fig. S2, cluster 2G), contain mostly acyl glucoses. Also, *S. habrochaites* type 1/4 trichomes contain largely acyl sucroses rather than acyl glucoses (Supplemental Fig. S2). As with the other trichome and species comparisons listed above, cultivated tomato type 1 glands are deficient in most of the specialized metabolites detected in this study.

Another trend evident in the type 1/4 comparison was the striking similarity between *S. habrochaites* type 1 and 4 trichomes at both the chemical and transcript levels (Figs. 3 and 4; Supplemental Fig. S2). While there were a few select compounds that exhibited differences in this comparison, such as a triacyl glucose with 20 acyl carbons, and two terpenoid metabolites tentatively assigned as glycosides of sesterterpene malonate esters, being more concentrated in type 1 than in type 4 (Supplemental Fig. S2, clusters 1A, 1B, and 2B), these differences were specific to only a few compounds and did not represent the overall metabolite profiles that were measured. As type 1 glandular trichomes are typically taller than type 4 trichomes, the relative differences in their metabolite contents may simply be a product of variation in cell size or trichome development.

Analysis of transcript levels (Supplemental Tables S6 and S7) demonstrated that the acyl sugar, phenylpropanoid, flavonoid, terpenoid, and specific alkaloid pathways are expressed in *S. habrochaites* type 1/4 glands, as are enzymes from core metabolism, as was observed for type 6 glands. Together, these data suggest that, like type 6 glands, *S. habrochaites* type 1/4 glands are most likely capable of both fixing carbon and metabolizing imported sugars. Not surprisingly, enzymes involved in the production of keto acids, fatty acids, lipids, and their subsequent derivatization are represented as well. Type 1/4 glands possess characteristic cuticle-enclosed heads that act as the site of the biosynthesis and storage of specialized metabolites, although these trichomes also apparently secrete the majority of the acyl sugars that are exuded from glands and coat the surface of *Solanum* leaves. The mechanism whereby these compounds are secreted from the gland cells has not yet been identified.

Comparison of transcript levels for annotated genes, whether from the EC or UPID standpoint, identified no significant differences between *S. habrochaites* type 1 and 4 glandular trichomes. Thus, the distinction of a trichome type as being either type 1 or 4 may be artificial. For this reason, comparisons to *S. lycopersicum* type 1 and *S. pennellii* type 4 were performed with a combined library referred as *S. habrochaites* type 1/4. Only one protein, a nonspecific lipid transfer protein, was preferentially expressed (in *S. lycopersicum* type 1 glands) in these comparisons. Not only was this the only gene with preferential expression in all of the *Solanum* type 1/4 comparisons, but it was also one of the most prevalent transcripts in all species sampled. It is no surprise that this particular protein is highly expressed, as it has been previously shown to be induced by both biotic and abiotic stress (Torres-Schumann et al., 1992; Ooi et al., 2008). Clearly, trichomes are exposed to “the weather” more than most cell types. In addition, the lack of differences in EST counts for UPID and EC annotations (Supplemental Figs. S15–S18) may be due to limited sampling of cells that were difficult to obtain. We expected to observe at least a few differences between species, considering the differences in metabolite content and quantities as shown in Figures 2 and 3 and Supplemental Table S2. An alternative explanation may be that regulation of compound production in this glandular trichome type may occur at levels not evaluated in this study, such as by protein turnover, biochemical control, substrate availability, or altered enzyme activity due to post-translational modifications.

Comparison of *Solanum* Type 6 and Type 1/4 Trichomes

To test for processes specific to either type 6 or type 1/4 glandular trichomes, we made three intraspecies comparisons (*S. lycopersicum* type 6 versus type 1, *S. habrochaites* type 6 versus type 1/4, and *S. pennellii* type 6 versus type 4; Supplemental Tables S18–S20) using the method of Stekel et al. (2000). Comparisons of type 6 and type 1/4 transcriptomes identified a limited number of significant differences between the trichome types in each of the three species. The
pennelli comparison between the Sanger type 6 and 4 libraries identified only one gene (A1XEL0_TOBAC) annotated as a cytochrome P450 of unknown function that was preferentially expressed in the type 6 gland (Supplemental Table S20). However, for the S. lycopersicum and S. habrochaites comparisons, which use two libraries of dissimilar size and sequencing methodologies, these comparisons must be more carefully considered. The results of the S. lycopersicum and S. habrochaites comparisons nevertheless demonstrate that a small number of known, annotated genes are preferentially expressed in either trichome type. Genes associated (Table II; Supplemental Tables S18 and S19) with the type 6 gland include several involved in terpenoid biosynthesis and stress response (B8XA40_SOLHA, Z,Z-farnesyl pyrophosphate synthase; Q9FQ28_SOLLC, sesquiterpene synthase 2; B8XA41_SOLHA, bergamotene/santAlene synthase; EC 2.4.1.115, anthocyanidin 3-O-glucosyltransferase; EC 1.10.3.1, catechol oxidase; and EC 1.13.11.12, Q96573_SOLLC, lipoxygenase [Stekel et al., 2000]). We have used the observation that transcripts of the S. lycopersicum homologs of B8XA40, B8XA41, and Q9FQ28 are abundant in type 6 glands of S. lycopersicum, but not in other S. lycopersicum glands, as the starting point to identify the enzymes responsible for the synthesis of monoterpenes in the type 6 glands, but not in other glands, of this species (Schilmiller et al., 2009). In that work, we used biochemical assays and genetic analysis of near-isogenic lines to show that the B8XA40 homolog in S. lycopersicum encodes neryl diphosphate synthase. Neryl diphosphate is used as the substrate by the Q9FQ28 homolog, a terpene synthase, to synthesize β-phellandrene and other monoterpenes.

On the other hand, both S. habrochaites and S. lycopersicum type 1/4 trichomes preferentially express a nonspecific lipid-transfer protein (NLTP1_SOLLC) when compared with type 6 glands; this gene may play an important role in the secretion of acyl sugars (Slocombe et al., 2008). Together, all three Solanum type 1/4 versus type 6 gland comparisons indicate that there appears to be no quantitative disparity in the expression of genes involved with specialized metabolite pathways, such as acyl sugar or terpenoid biosynthesis (Table II). In addition, the preferential expression of a nonspecific lipid-transfer protein in type 1/4 trichomes in two of the three species is not surprising given the secretory activity of this trichome type, as evidenced by acyl sugar exudate accumulation on the leaves of these species, and may implicate this gene in the secretory activity of these cells.

It is important to note that some of the individual type 1 and 4 gland EST databases are limited in size, so that the prevalence of some transcripts that are not highly represented could not be reliably compared with that in other types of glands. For example, we recently showed by quantitative PCR that a rare transcript found in the S. habrochaites type 4 trichome EST database is nevertheless present in type 1 and 4 trichomes at about a 10-fold higher level than in type 6 trichomes. Biochemical assays showed that the transcript encodes an enzyme that methylates myricetin, thus explaining the above-noted observation that type 1 and 4 glands of S. habrochaites contain severalfold higher levels of methylated myricetin than do type 6 glands (A. Schmidt and E. Pichersky, unpublished data).

Characterization of Solanum Type 7 Trichomes

The type 7 glandular trichome is a short, multicelled trichome (Fig. 1M) that has been largely uncharacterized. We were able to collect type 7 trichomes from S. habrochaites for metabolite and transcriptome profile analysis. However, this gland type was either absent or too difficult to obtain from the other species to be included in our analysis. Surprisingly, type 7 glands from S. habrochaites were found to possess considerably higher concentrations of most metabolite classes than many of the other trichome types from the other species (Figs. 2 and 3). However, most of the compounds observed were also present at similar levels in other trichome types from S. habrochaites, suggesting contamination by the exudates produced by type 1/4 glands. The exceptions were the alkaloids tomatine and dehydrotomatine (Supplemental Fig. S2, cluster 2B), which were present in S. habrochaites type 7 glands but essentially absent from all other glandular trichome types.

Further investigations into the biological roles of this particular glandular trichome type led us to sequence 1,980 ESTs using the Sanger method and analyze chemical extracts from individually isolated S. lycopersicum type 7 glands. This analysis revealed that this gland type contains few if any transcripts with gene ontologies associated with specialized metabolism (Supplemental Fig. S19; Supplemental Tables S21–S24). In contrast, Cys protease inhibitors were strongly up-regulated in this trichome type, suggesting a role separate from the other glandular trichome types in plant defense.

CONCLUSION

The type 6 and type 1/4 trichomes from the Solanum species analyzed in this study contain somewhat overlapping and modular sets of specialized metabolites, particularly acyl sugars, when compared within species. Despite this overlap, there are quantitative differences in metabolite profiles between Solanum species. These differences mirror previously determined Solanum phylogenies (Ferialta and Spooner, 2001; Medeiros and Tingey, 2006). Glandular trichomes of S. habrochaites contain the most diverse sets of acyl sugars, fatty acids, alkaloids, and terpenoids compared with all other species, with sesterterpenes and acyl sucroses as the dominant forms of their respective metabolite classes (terpenoids and acyl sugars). (Table continues on following page.)
species with the second most diverse array of specialized metabolites is *S. pennellii*, dominated by the acyl glucose class of compounds. The remaining two wild species, *S. arcanum* and *S. pimpinellifolium*, have metabolite profiles that are very similar to *S. lycopersicum* and possess only modest differences when compared with their domesticated counterpart. Also, the transcriptomes of each of the trichome types generally mirror their respective biochemistries. Analysis of the glandular trichome EST collections reveals that all of the type 1/4 and 6 glands appear to contain most of the genes necessary for specialized metabolite biosynthesis, such as for the acyl sugar, terpenoid, or flavonoid pathways. More quantitative transcript comparisons (Supplemental Tables S14–S20) between species and gland types indicate that distinct chemical profiles may be due to differential regulation of specific genes or gene pathway segments on a transcriptional level or by other processes that are not directly connected to transcription, such as posttranslational modification of proteins, protein turnover, or biochemical control and cross-talk between pathways, among other possibilities.

Notable differences between different glandular trichome types were observed within species. For example, *S. lycopersicum* type 1 glandular trichomes are dominated by acyl glucose (although even these compounds were present at relatively low levels in this trichome type from this species), while type 6 glands from this species are dominated by acyl sucroses. Complementary analysis of type 6 gland transcripts across species mirrored some of the traits observed in the different species’ metabolite profiles. Unfortunately, the comparison of metabolite levels with transcript levels was unable to identify specific genes whose expression levels could explain the differences in acyl sucrose and acyl glucose content for *S. habrochaites* or *S. pennellii* type 6 trichomes. Thus, unlike terpenoid biosynthesis in *S. habrochaites*, control of acyl sugar metabolism is likely exerted at a level not observable by the transcriptome analysis used in this study, a fact observed in the type 1/4-type 6 transcript comparisons of *S. lycopersicum* and *S. habrochaites*. However, this conclusion may be limited due to the small sampling size of the type 1/4 EST collections.

Many of the genes involved in photosynthesis and carbon fixation are expressed at significant (although not particularly high) levels in the *Solanum* trichome types investigated, in contrast to what has been observed in some other species (Turner et al., 2000; Gang et al., 2001; Deschamps et al., 2006; Gunnewich et al., 2007; Marks et al., 2009). Therefore, it is likely that at least some of the carbon required for the synthesis of the specialized metabolites found in *Solanum* glandular trichomes may be fixed within the trichome secretory cells. The relationship between de novo carbon fixation and import of Suc as the source for carbon skeletons, however, remains to be determined.

The least characterized of all glandular trichome types, the type 7 glandular trichome, appears to have a more limited metabolite profile than the other types. Because of the method required to collect type 7 glands, we cannot be sure that the type 7 transcriptome and metabolic profile sampled are completely exclusive to the type 7 gland. Nevertheless, it is clear that specialized metabolite production is limited in this glandular trichome type compared with the other types.

Finally, the distinction between type 1 and type 4 glandular trichomes, at least in *S. habrochaites*, may represent an artificial classification system, due to the lack of wholesale differences between the metabolic profile or the transcriptome of either cell type. Therefore, it may be more reasonable to consider type 4 glandular trichomes as simply a morphotype of a larger type 1 class.

### MATERIALS AND METHODS

#### Plants and Growth Conditions

All *Solanum* germplasm used in this study was obtained from the C.M. Rick Tomato Genetics Resource Center. Seeds were treated with 10% sodium tripolyphosphate for 20 min and rinsed in 10% bleach for 1 min. After rinsing thoroughly with sterile water, seeds were spread out on moist 3M Whatman filter paper in a sealed container. After 4 to 5 d, the seeds were transferred to peat pellets. The plants were grown in a growth room under a 16-h-light (27°C)/8-h-dark (18°C) cycle with the light intensity at approximately 200 μE m⁻² s⁻¹. Plants in peat pellets were watered daily with Peter’s Professional general purpose 20:20:20 diluted to give 100 μL L⁻¹ nitrogen. After 3 to 4 weeks, depending on the species, seedlings were transferred to 4-inch square pots and grown in the same growth room until analysis.

#### Production of 454 Libraries

Production of 454 libraries was exclusive to the type 6 trichome for all species except *Solanum pennellii*. For *Solanum lycopersicum*, *Solanum arcanum*,
**Production of Sanger Libraries**

In order to prepare the remaining glandular trichome EST libraries from *S. lycopersicum*, *S. pennellii*, and *S. habrochaites*, a protocol utilizing stretched glass pipettes (Supplemental Fig. S20) or microwells (for accessions where the glands would not stick to the glass pipettes) was used to collect samples, consisting of 4,000 each of type 1 (*S. lycopersicum*, *S. habrochaites*), type 4 (*S. pennellii*, *S. habrochaites*), and type 6 (*S. pennellii*) trichomes. These were transferred immediately into RNAlater and stored at −80°C until processed using the Qiagen RNEasy kit. Again, the resulting cDNA synthesis was performed using the protocol described by Kapteyn et al. (2010) and sequenced by 454 sequencing (QS FLX) at the Michigan State University Research Technology Support Facility.

**LC-MS Analysis of Trichome Extracts**

*S. habrochaites* type 7 trichomes were collected in the manner described above, transferred to a microfuge tube, spun down (3,000g, 30 s), and resuspended in extraction solvent after the wash buffer was removed. For the remaining trichome types, picked trichome fractions of approximately 15 to 20 g of young leaves of *S. lycopersicum*, *S. pennellii*, *S. habrochaites* were collected in the manner described above, transferred to a microfuge tube, spun down (3,000g, 30 s), and resuspended in extraction solvent after the wash buffer was removed. For each type 6 trichomes collected on the final 33-μm mesh, the type 6 trichome fraction was immediately transferred to RNAlater and stored at −80°C until processed using the Qiagen RNEasy kit. cDNA was synthesized according to the protocol described by Kapteyn et al. (2010) and then subcloned into the pCR2.1 vector.

*S. lycopersicum* type 7 trichome fractions used for EST analysis were produced in a manner similar to those of the *Solanum* type 6 fractions described above; however, an additional set of filters was added to further remove as many type 1, 6, and hairy trichomes as possible from the initial type 7 flow-through. Additional steps include further filtration through a 75-μm and a 35-μm mesh. The final, enriched type 7 fraction was collected on the 33-μm mesh and used to produce cDNA as described (Kapteyn et al., 2010).
