The oceans take up more than 1 million tons of CO₂ from the air per hour, about one-quarter of the anthropogenically released amount, leading to disrupted seawater chemistry due to increasing CO₂ emissions. Based on the fossil fuel-intensive CO₂ emission scenario (A1F1; Houghton et al., 2001), the H⁺ concentration or acidity of surface seawater will increase by about 150% (pH drop by 0.4) by the end of this century, the process known as ocean acidification (OA; Sabine et al., 2004; Doney et al., 2009; Gruber et al., 2012). Seawater pH is suggested to decrease faster in the coastal waters than in the pelagic oceans due to the interactions of hypoxia, respiration, and OA (Cai et al., 2011). Therefore, responses of coastal algae to OA are of general concern, considering the economic and social services provided by the coastal ecosystem that is adjacent to human living areas and that is dependent on coastal primary productivity. On the other hand, dynamic environmental changes in the coastal waters can interact with OA (Beardall et al., 2009).

Macroalgae have diversified strategies in terms of inorganic carbon (Ci) acquisition, with different carboxylation efficiencies associated with different photosynthetic affinities for Ci (Johnston and Raven, 1990; Giordano et al., 2005; Zou and Gao, 2010). Most macroalgae can actively use bicarbonate or directly take up CO₂ to provide a CO₂ source for Rubisco, a mechanism known as the carbon-concentrating mechanism (CCM), while a few red and green macroalgae, known as “non bicarbonate users,” acquire Ci solely by diffusion of dissolved CO₂ (Raven et al., 1995; Kübler et al., 1999). Therefore, macroalgae may respond differentially to increasing pCO₂ (for partial pressure of CO₂ in seawater) and the changing chemistry of seawater. Increasing atmospheric CO₂ concentrations have been demonstrated to enhance the photosynthesis of intertidal macroalgae at low tide during emersion (Gao et al., 1999; Zou and Gao, 2005) and enhance the growth of the red alga Porphyra yezoensis, Gracilaria spp., and Lomentaria articulata (Gao et al., 1991, 1993; Kübler et al., 1999) and the brown alga Hizikia fusiforme (Zou, 2005). However, decreased growth rates under elevated CO₂ concentrations are observed in Gracilaria tenuistipitata (García-Sánchez et al., 1994), Porphyra leucostica (Mercado et al., 1999), and Porphyra linearis (Israel et al., 1999). Neutral effects of elevated CO₂ levels (750 μatm) on the growth of several macroalgae are also reported (Israel and Hophy, 2002). Recent research shows that meiospore germination in the brown macroalga Macrocystis pyrifera benefits from the increased availability of CO₂ (820 μatm; Roleda et al., 2012). Despite these differential responses, OA is notorious for reducing calcification of the red coralline algae (Gao et al., 1993; Gao and Zheng, 2010), green Halimeda spp. (Sinutok et al., 2011), and brown Padina spp. (Johnson et al., 2012). Furthermore, elevated CO₂ has the potential to influence competition between non-calcareous macroalgae and coralline species (Hepburn et al., 2011).

Marine green algae represent a large paraphyletic group of green plants from which the higher plants (the embryophytes) developed (Douglas et al., 2004). They share the same photosynthetic pigments with, but live in a quite different environment from, terrestrial higher plants. These plants, mostly distributed in coastal waters, where biological production is high, experience dynamic environmental changes associated with reciprocal tides and human activities. In most coastal waters, because of the photosynthetic carbon removal from and respiratory carbon release to the ambient environment, fluctuation of pH usually shows a day-night (high to low) reversion pattern. Therefore, marine green algae are usually tolerant to acid-base perturbations (Larsson et al., 1997), although the mechanisms involved are not understood yet. From a physiological point of view, marine green algae may show fairly different responses from terrestrial plants to increasing CO₂ concentration, if acidity change acts to affect their physiology. However, to our knowledge, little has been documented on this aspect.

Increased availability of ambient CO₂ to about 1,000 μatm based on the projected future atmospheric CO₂ rise may not be large enough to affect the influx of CO₂.

into cells because of the operation of CCMs, which will result in concentrated CO₂ within the cells (Raven et al., 2011). Although CCMs can be down-regulated under elevated CO₂ levels, they are supposed not to have been switched off (Wu et al., 2012), and intracellular CO₂ concentration and energetics for algal growth can be altered (Hopkinson et al., 2011; Raven et al., 2011). On the other hand, increased external acidity associated with the enrichment of CO₂ would either exert a stress that influences intracellular acid-base stability (Gao et al., 2012) or ease the acid-base regulation, since most algae maintain an average pH across the cell of between 7 and 7.5 (Smith and Raven, 1979). Therefore, energetics can also be affected due to changes of pH in the ambient environment. At the same time, the oxygenation process might be enhanced, since the CO₂-to-oxygen ratio surrounding Rubisco may be changed due to the down-regulation of CCMs. Based on the above theoretical assumptions, we hypothesize that the effects of future CO₂-induced OA on marine green algae will depend on light levels due to affected energetics associated with the down-regulation of CCMs as well as acid-base regulation; therefore, dark- and light-dependent respiration would be enhanced under stressful light levels due to changes in the algae’s energetics to cope with the increased acidity. We chose the green macroalga Ulva prolifera (Zhang et al., 2011), which is commonly found in the coastal waters of the Pacific Ocean, to test this hypothesis. This species is also notorious for forming large-scale green tides (Lu and Qiao, 2008) in recent years.

growth light level (100 μmol photons m\(^{-2}\) s\(^{-1}\)), electron transport rate (ETR) was higher (\(P = 0.001\)), while nonphotochemical quenching (NPQ) was significantly lower (\(P = 0.04\)), and no significant difference (\(P = 0.6\)) was found in the net photosynthetic (oxygen evolution) rate between the high-CO\(_2\) (HC)- and low-CO\(_2\) (LC)-grown plants. Under the high light levels (600 μmol photons m\(^{-2}\) s\(^{-1}\)), both the ETR and NPQ were higher (\(P = 0.01\)), while the net photosynthetic oxygen evolution rate was significantly lower (\(P = 0.046\)) in the HC-grown plants (Fig. 2). When measured at the ambient CO\(_2\) level (pH 8.2), the light-saturated photosynthetic oxygen evolution rate (\(P_{\text{max}}\)) and the apparent photosynthetic light use efficiency \(\alpha_{\text{P}}\) were significantly (\(P = 0.005\) and 0.023, respectively) lower (Fig. 3A; Table I). However, the light-saturated ETR (ETR\(_{\text{max}}\)) and electron transport efficiency \(\alpha_{\text{ETR}}\) were higher (\(P = 0.01\) and 0.038, respectively; Fig. 3B; Table I) in HC-grown than in LC-grown individuals. When examined in a CO\(_2\)-free medium (pH 8.2), the ETR decreased immediately, with the depletion of the intracellular Ci pool within 5 min, and was then sustained for the following 4 h, with the rate of the HC-grown plants being significantly (\(P = 0.01\)) higher by 45% than that in the LC-grown ones (Fig. 4). The HC-grown alga increased their NPQ to a much higher extent (about twice) compared with the LC-grown ones when exposed to stressful high-light levels (Fig. 5), reflecting that the HC condition led to additional light stress.

When light-dependent (photorespiration) and dark respirations were compared, the HC-grown thalli showed a higher (by 52%; \(P = 0.017\)) photospiration rate than the LC-grown ones, but no significant (\(P = 0.41\)) difference was found in the dark respiration (Fig. 6).

The relationship of photosynthetic oxygen evolution versus dissolved Ci concentration (Fig. 7A) showed higher \(K_{1/2\text{DIC}}\) or \(K_{1/2\text{CO}_2}\), reflecting reduced photosynthetic dissolved Ci (DIC) affinity (Fig. 7B), in the
HC-grown plants. Such a reduced photosynthetic affinity for DIC and/or CO₂ indicated a down-regulated CCM or a decrease in CCM activity. The efficiency of Ci acquisition, reflected by the ratio of $V_{\text{max}}$ to half-maximal photosynthetic rate $(K_{\text{m}})$ for both DIC and CO₂, decreased significantly $(P = 0.0001)$ in the HC-grown plants, by up to 31%.

The contents of chlorophyll (Chl) $a$ and Chl $b$ decreased $(P = 0.039$ and 0.004, respectively), while that of carotenoids increased $(P = 0.032)$ in the HC-grown thalli (Fig. 8A). The Chl $a/b$ ratio in the thalli grown in the LC condition was significantly lower than that in the HC condition $(P = 0.001$; Fig. 8B).

POSSIBLE MECHANISMS AND IMPLICATIONS

The green alga *U. prolifera*, when grown under the elevated CO₂ concentration in a controlled seawater carbonate system, showed enhanced growth (Fig. 1) and reduced its maximal photosynthetic oxygen evolution rate and light use efficiency (Figs. 2A and 3A; Table 1) as well as its efficiency to dissipate excessive light energy (Figs. 2C and 5), although acclimation to the elevated CO₂ level led to a higher electron transfer rate under the growth light level (Figs. 2B and 3B), which is consistent with that previously reported by Liu et al. (2012) for the same species grown under the same CO₂ levels. Consumption or reduction of O₂ by both photorespiration and the Mehler reaction must have played a critical role in photoprotection, sustaining the electron flow (Ort and Baker, 2002). The fact that the sustained ETR was much higher in the HC-grown than in the LC-grown plants, even in the CO₂-free medium, reflected that these pathways were enhanced under the HC condition. Photorespiration was indeed much higher in the HC-grown than in the LC-grown plants (Fig. 6). On the other hand, light-stimulated synthesis of photosynthetic pigments (Fig. 8) and/or enhanced photorespiration in the HC-grown thalli did lead to decreased oxygen evolution at the subsaturating and saturating light levels (Fig. 7), although their ETR increased either at deprived (Fig. 4) or elevated (Liu et al., 2012) DIC levels. Since the operation of CCMs demands energy and concentrated intracellular CO₂ can acidify the thylakoid lumen, an essential component of the CCM (Raven, 1997), down-regulation of CCM in the HC-grown thalli might have decreased the intracellular CO₂ level and have contributed to lower the NPQ at the same time. HC-grown red alga *P. yezoensis* showed decreased oxygen evolution rate (K. Gao, unpublished data), although its growth rate was stimulated (Gao et al., 1991). A cyanobacterium grown at an elevated DIC level also decreased its net photosynthetic reductant production (Mackenzie et al., 2004). The enhanced growth rate of *U. prolifera* might be attributed to the energy saved due to the down-regulated CCM operation as well as nitrogen metabolism. Elevated CO₂ concentrations stimulated the uptake of NO₃⁻ in another *Ulva* species, *Ulva rigida* (Gordillo et al., 2001), and enhanced the activity of nitrate reductase in *U. rigida* (Gordillo et al., 2001, 2003) and *Ulva linza* (data not shown).

The persistence of photosynthetic electron transport without supply of ambient Ci from the ambient environment (Fig. 4) indicated the involvement of some pathways that continuously drained the electrons when the plants were exposed to oversaturating light levels. HC-grown plants grown for 2 months at ambient (LC; 390 μatm) and elevated (HC; 1,000 μatm) CO₂ levels. Consumption or reduction of O₂ by both photorespiration and the Mehler reaction must have played a critical role in photoprotection, sustaining the electron flow (Ort and Baker, 2002). The fact that the sustained ETR was much higher in the HC-grown than in the LC-grown plants, even in the CO₂-free medium, as well as the down-regulated CCM activity, reflected that these pathways were enhanced under the HC condition. Photorespiration was indeed much higher in the HC-grown than in the LC-grown plants (Fig. 6).
of fatty acids might also play a role in additional electron drainage (Willms et al., 1999).

The elevated CO₂ concentrations, projected for the end of this century, are known to down-regulate algal CCMs (Rost et al., 2003; Wu et al., 2010), but they may not be adequate to supply enough CO₂ by diffusion to sustain intracellular CO₂ concentrations. While intracellular Ci pools might be reduced in HC-grown algae to below that in the LC-grown ones (Spijkerman, 2011; Raven et al., 2012), intracellular CO₂ availability around Rubisco in U. prolifera would have decreased under OA, so that the photosynthetic oxygen evolution rate was reduced (Figs. 2A and 3A) and photorespiration was enhanced (Fig. 6). On the other hand, the enhancement of ETR in the HC-grown plants (Figs. 2B, 3B, and 4) indirectly indicated that the enhancement of photorespiration or other metabolic pathways, such as the water-water cycle (Asada, 1999), led to additional electron drainage while playing the photoprotective role under excessive light conditions (Crawley et al., 2010). At the same time, NPQ increased faster in the HC-grown plants (Figs. 2C and 5). Stimulated NPQ and photorespiration under OA were recently noted in diatoms and phytoplankton assemblages when exposed to high light levels (Gao et al., 2012).

Under growth subsaturating light, down-regulated CCM due to increased external CO₂ availability might have saved some energy for its operation, and this saved energy, such as ATP generated by transmembrane H⁺-ATPase, could be used for carboxylation, leading to decreased energy-dependent nonphotochemical quenching (the key component of NPQ; Kanazawa and Kramer, 2002) and increased ETR (Fig. 2B; Liu et al., 2012) and growth (Fig. 1). However, when the alga was exposed to excessive light levels, enhanced defensive pathways under the OA condition, such as photorespiration and NPQ, as well as the synthesis of carotenoids would have taken their toll on the energetics (Figs. 6 and 8A). At the same time, the alga decreased its light-capture pigments (Fig. 8A). Such a “pigment economy” phenomenon could avoid the overexcitation of electron transport as a sign of adaptation, and reduction of the antenna size and an increase in the Chl a/b ratio (Fig. 8B) provided further evidence to support this.

For terrestrial green plants, short-term exposures to increased CO₂ levels stimulate the net photosynthesis of both C₃ and even some C₄ plants (Ziska and Bunce, 2006), while long-term exposures to elevated CO₂ concentration often lead to a declined photosynthetic rate in many plant species (Thomas and Strain, 1991). Dark respiration and photorespiration are also reduced at the leaf level, while plant growth is stimulated (Bunce, 2004). In addition, intracellular acid-base regulation is affected by elevated CO₂ levels in C₃ higher plants (Yin et al., 1990). In contrast, the green alga U. prolifera has to cope with both decreasing pH and increasing partial pressure of CO₂ in the marine environment because of the atmospheric CO₂ rise. Such an acid-based perturbation would affect ion channels across the cell membrane and the associated
Physiological Response of a Green Alga to $pCO_2$

energetic cost in order to maintain intracellular pH stability; therefore, OA can be a stressor for marine plants, although it may favor their energy budget when light energy is limited (Gao et al., 2012). When other environmental stressors, such as excessive light, coexisted with OA, the green alga’s defensive strategy was enhanced (Figs. 2B, 5, and 6). From an evolutionary point of view, advantage to the green plants evolving to terrestrial environments might have been avoidance of the stress of OA, which is known to have occurred at the end of the Ordovician period (Veron, 2008). Green plants have been suggested to have evolved about 400 million years ago (Leliaert et al., 2011), when atmospheric $CO_2$ was as high as 3,000 $\mu$L L$^{-1}$ and the extinction of marine organisms occurred with an ancient OA event (Berner, 2006; Veron, 2008).

In the natural environment, although $U.\ prolifera$ can tolerate some extent of pH change, increasing seawater acidity due to the ongoing atmospheric $CO_2$ rise would lower the baseline of coastal pH and challenge most organisms’ ability to acclimate or adapt to coastal OA, which is suggested to proceed faster than in the pelagic waters (Cai et al., 2011). Our study obviously demonstrates that OA mediated the photochemical and photorespiratory pathways of the green alga grown under OA conditions, but how this affects its life cycle (interchange of sporophyte and gametophyte life stages) remains to be investigated.

MATERIALS AND METHODS

Thalli and Culture Conditions

Thalli of $U.\ prolifera$ were collected in June 2009 from the coastal water of Lianyungang (119.5°E, 34.5°N), Jiangsu province of China, where the alga caused a green tide (Keesing et al., 2011). Selected thalli were cleaned of epiphytes and cultured in the laboratory at 100 $\mu$mol photons m$^{-2}$ s$^{-1}$ with 15% illumination. After adhesion, the spores were cultured under ambient (390 ppm $CO_2$) CO$_2$ levels and at the above light and temperature conditions. The HC level was obtained in a CO$_2$ plant chamber, which automatically controlled the CO$_2$ concentration in it with variation of less than 5%. The LC level was obtained by pumping the ambient air from the laboratory at 8.18 and 7.82 in the LC and HC cultures, respectively, with variations of less than 0.04, by constantly removing increased algal biomass and renewing the seawater (30% salinity, pH 8.2, 1.9 mM DIC) for determining the net photosynthetic rate as a function of light (P-E curve), and the temperature was controlled at 20°C. The net photosynthetic rate was also measured in seawater medium equilibrated with either high (1,000 ppm) or low (390 ppm) $CO_2$ levels under growth light (100 $\mu$mol photons m$^{-2}$ s$^{-1}$) and high light (600 $\mu$mol photons m$^{-2}$ s$^{-1}$). The photosynthesis-versus-DIC concentrations curve was measured by adding sodium bicarbonate solution into DIC-free seawater medium buffered with 20 mM Tris (pH 8.2) at final DIC concentrations within a range of 0 to 8.8 mmol L$^{-1}$. Parameters for the P-E curves were analyzed as follows (Jassby and Platt 1976):

$$\text{P} = \text{P}_{\text{max}} \times \text{tanh}(a \times \text{E}/\text{P}_{\text{max}}) + \text{R}_d,$$

where $P$ is the photosynthetic rate, tanh is the hyperbolic tangent, $E$ is the irradiance, and $R_d$ is the dark respiration rate. The $K_{i/2}$ (reciprocal of photosynthetic affinity) values for DIC or $CO_2$ were calculated using the Michaelis-Menten equation.

Determination of Photorespiration

Photorespiration was estimated as the difference in net photosynthetic oxygen evolution of the thalli at reduced (2%) and ambient (21%) $O_2$ levels (Drew et al., 1993). The Tris-buffered seawater (pH 8.2) was flushed with either pure $N_2$ or air to establish the low (2%) or air-saturated (21%) levels of dissolved $O_2$. Oxygen concentration was measured as above.

Chl Fluorescence Measurements

After 10 min of dark adaptation, fluorescence induction curves were measured with a xenon-pulse amplitude-modulated fluorometer (Walz) for examining the photochemical performance of $U.\ prolifera$ grown at different $CO_2$ levels. The actinic light was set at 100 and 600 $\mu$mol photons m$^{-2}$ s$^{-1}$, respectively, and the saturating light was 5,000 $\mu$mol photons m$^{-2}$ s$^{-1}$. The $F_o$ is maximum fluorescence yield after dark adaptation and $F_{m\prime}$ is the maximum fluorescence yield under actinic light. The $E$ was calculated as follows (Genty et al., 1989):

$$\text{E} = \text{P}_{\text{max}} \times (1 - e^{-t'/t})\text{R}_{\text{d}},$$

where $a$ is the efficiency of electron transport and $E$ is the irradiance. To investigate the ETR in $CO_2$-free seawater, DIC-free seawater was measured by adding 1.0 mM HCl to lower the pH to less than 3.0, then sparging for at least 1 h with high-purity $N_2$ gas, and buffering with 20 mM Tris (pH 8.2).

Determination of Photosynthetic Pigments

About 100 mg fresh weight of thalli was extracted with 10 mL of absolute methanol at 4°C for 24 h in darkness, and Chl $a$, Chl $b$, and carotenoid concentrations were estimated according to Wellburn (1994).

Data Analysis

The data are shown as means ± sd of three measurements. Statistical analysis was performed with one-way ANOVA (Tukey’s) or Student’s $t$ test. The 95% confidence level was used in all analyses.
