ABSTRACT

Maize is an excellent cereal model for research on seed development due to its relatively large size for both embryo and endosperm. Despite the importance of seed in agriculture, the genome-wide transcriptome pattern throughout seed development has not been well characterized. Using RNA-seq, we developed a spatio-temporal transcriptome atlas of B73 maize seed development based on 53 samples from fertilization to maturity for embryo, endosperm, and whole seed tissues. A total of 26,105 genes were found to be involved in programming seed development, including 1,614 transcription factors. Global comparisons of gene expression highlighted the fundamental transcriptomic reprogramming and the phases of development. Coexpression analysis provided further insight into the dynamic reprogramming of the transcriptome by revealing functional transitions during maturation. Combined with the published non-seed RNA-seq data, we identified 91 transcription factors and 1,167 other seed-specific genes, which should help elucidate key mechanisms and regulatory networks that underlie seed development. Additionally, correlation of gene expression with the pattern of DNA methylation revealed that hypomethylation of the gene body region should be an important factor for the expressional activation of seed-specific genes, especially for extremely highly expressed genes such as zeins. This study provides a valuable resource for understanding the genetic control of seed development of monocotyledon plants.
Maize (Zea mays) is one of the most important crops and provides resources for food, feed and biofuel (Godfray et al., 2010). It has also been used as a model system to study diverse biological phenomena, such as transposons, heterosis, imprinting, and genetic diversity (Bennetzen and Hake, 2009). The seed is a key organ of maize which consists of the embryo, endosperm and seed coat. Maize seed development initiates from a double fertilization event where two pollen sperm fuse with the egg and central cells of the female gametophyte to produce the progenitors of the embryo and endosperm, respectively (Dumas and Mogensen, 1993; Chaudhury et al., 2001). The mature embryo inherits the genetic information for the next plant generation (Scanlon and Takacs, 2009), while the endosperm, which is storage tissue for the embryo, persists throughout seed development and functions as the site of starch and protein synthesis (Sabelli and Larkins, 2009). Elucidation of the genetic regulatory mechanisms involved in maize seed development will facilitate the design of strategies to improve yield and quality, and provide insight applicable to other monocotyledon plants.

A key means to explore the mechanisms of seed development is to identify gene activities and functions. Genetic studies have uncovered a number of genes that play major roles in governing embryogenesis and accumulation of endosperm storage compounds, such as Viviparous1 (Vp1), KNOTTED1 (KN1), Indeterminate gametophyte1 (Ig1), Shrunken1 (Sh1), Opaque2 (O2), Defective kernel 1 (Dek1) (Chourey and Nelson, 1976; McCarty et al., 1991; Smith et al., 1995; Vicente-Carbajosa et al., 1997; Lid et al., 2002; Evans, 2007). Furthermore, the activity of some genes also has been extensively studied. Typical examples are zein genes that encode primary storage proteins in endosperm. Woo et al. (2001) examined zein gene expression and showed they were the most highly expressed genes in endosperm based on expressed sequence tag (EST) data, while their dynamic expression patterns were revealed in a later study (Feng et al., 2009). Nevertheless, information on the global gene expression network throughout seed development is still very limited.

The transcriptome is the overall set of transcripts, which varies based on cell or
tissue type, developmental stage and physiological condition. Analysis of transcriptome dynamics aids in implying the function of unannotated genes, identifying genes that act as critical network hubs, and interpreting the cellular processes associated with development. In *Arabidopsis thaliana*, the genes expressed in developing seed and its subregions at several development stages have been analyzed with Affymetrix GeneChips (Le et al., 2010; Belmonte et al., 2013). In maize, microarray based atlases of global transcription have provided insight into the programs controlling development of different organ systems (Sekhon et al., 2011). Compared to microarray, RNA-seq is a powerful tool to comprehensively investigate the transcriptome at much lower cost, but higher sensitivity and accuracy (Wang et al., 2009). Several studies have taken advantage of RNA-seq strategy to interpret the dynamic reprogramming of transcriptome during leaf, shoot apical meristem (SAM) and embryonic leaves development in maize (Li et al., 2010; Takacs et al., 2012; Liu et al., 2013).

However, as of yet, only two studies have focused on identifying important regulators and processes required for embryo, endosperm and/or whole seed development in maize based on genome-wide transcriptional profile produced by RNA-seq (Liu et al., 2008; Teoh et al., 2013). However, these studies were limited by the low number of samples used and they did not provide an extensive, global view of transcriptome dynamics over the majority of seed development stages. Here, we present a comprehensive transcriptome study of maize embryo, endosperm and whole seed tissue from fertilization to maturity using RNA-seq, which serves as a valuable resource for gene function analysis on a global scale and elucidating the developmental processes of maize seed.

**RESULTS**

**Generation and Analysis of RNA-seq Dataset**

To systematically investigate the dynamics of the maize seed transcriptome over development, we generated RNA-seq libraries of B73 seed tissues from different developmental stages, including 15 embryo, 17 endosperm and 21 whole seed samples (Fig. 1). Utilizing paired-end Illumina sequencing technology, we generated
around 1.9 billion high-quality reads, 80.2% of which could be uniquely mapped to the B73 reference genome (Schnable et al., 2009) (Supplemental Table S1). The genic distribution of reads was 66.6% exonic, 25.6% splice junction and 2.6% intronic, leaving about 5% from unannotated genomic regions, demonstrating that most of the detected genes have been annotated. Uniquely mapped reads were used to estimate normalized transcription level as reads per kilobase per million (RPKM). To reduce the influence of transcription noise, genes from the B73 filtered gene set (FGS) were included for analysis only if their RPKM values were \( \geq 1 \). Considering that our purpose was not to identify minor differential expression of genes between two time points of development, but to provide an atlas of gene expression profile across tissues using time series biological samples, we only randomly selected twelve samples to have a biological replicate (Supplemental Fig. S1) to assess our data quality. Comparisons of biological replicates showed that their expression values were highly correlated (average \( R^2 = 0.96 \)). For the samples with biological replicates, we took the average RPKM as expression quantity. To further evaluate the quality of our expression data, we compared the transcript abundance patterns of a number of selected genes with previously measured expression profiles (Supplemental Fig. S2). For example, **LEAFY COTYLEDON1** (**LEC1**), which functions in embryogenesis, was mainly expressed in the early stage of embryo (Lotan et al., 1998). **Globulin2** (**Glb2**), had high expression late in embryogenesis, in accordance with its function as an important storage protein in the embryo (Kriz, 1989). Similarly, **O2**, a transcription factor (**TF**) that regulates zein synthesis (Vicente-Carbajosa et al., 1997), and **Fertilization independent endosperm1** (**Fie1**), a repressor of endosperm development in the absence of fertilization (Danilevskaya et al., 2003), were almost exclusively expressed in the endosperm. Expression patterns of these selected genes were identified exclusively in their known tissue of activity, indicating that the embryo and endosperm samples were processed well.

In total, we detected 26,105 genes expressed in at least one of the 53 samples (Supplemental Data Set S1). The distribution of these genes is revealed by the Venn diagram (Fig. 2A), which shows 20,360 genes were common among all three tissue...
types. The number of genes detected in endosperm tissue during the developmental stages was lower and much more variable compared with embryo or whole seed tissue, and a greater number of genes were expressed in the tissue during the early and late phases. Several thousand fewer expressed genes were detected 14 days after pollination (DAP) in the endosperm compared with 6 or 8 DAP (Fig. 2B; Supplemental Data Set S2). In addition, the median expression level in the embryo was roughly 2 fold greater than that of the endosperm from 10 to 30 DAP (Fig. 2C). Of the 1,506 genes unique to the whole seed samples, 451 were present in RNA-seq data of 14 and/or 25 DAP pericarp tissue (Morohashi et al., 2012). Considering that the vast majority content of the early seed is the maternal tissue (Márton et al., 2005; Pennington et al., 2008), we inferred that most of these genes might be expressed exclusively in maternal tissue, such as the pericarp or nucellus. Moreover, 1,062 genes in the embryo and endosperm with low expression were not detected in whole seed samples (Fig. 2C).

**Division of Development Phases by Global Gene Expression Patterns**

To gain insight into the relationships among the different transcriptomes, we performed principal component analysis (PCA) on the complete dataset, which can graphically display the transcriptional signatures and developmental similarity. The first component (40.7% variance explained) separated samples based on tissue identity and clearly distinguished embryo from endosperm samples, with whole seed samples located in between (Fig. 3A). The second component (24.4% variance explained) discriminated early, middle and late stages of development for all three tissues (Fig. 3A). The wider area occupied by endosperm samples than embryo demonstrates a stronger transcriptome reprogramming in developing endosperm, which is mainly due to drastic changes in the early and late stages. Moreover, whole seed samples of 0 to 8 and 30 to 38 DAP clustered closely to the embryo, but 10 to 28 DAP samples were close to the endosperm.

Cluster analysis of the time-series data for the tissues grouped samples well along the axis of developmental time (Fig. 3, B-D). Embryo samples from 10 to 20 DAP and 22 to 38 DAP were the primary clusters, which correspond to morphogenesis and
maturation phases of development (Fig. 3B). This is consistent with the embryo undergoing active DNA synthesis, cell division and differentiation, and then switching to synthesis of storage reserve and desiccation (Vernoud et al., 2005). Expression differences in endosperm samples resulted in three primary clusters, which correspond to early, middle, and late phases of development (Fig. 3C). The earliest time points, 6 and 8 DAP, is an active period of cell division and cell elongation that terminates at about 20 to 25 DAP (Duvick, 1961). The samples of 10 to 24 DAP formed one subgroup and 26 to 34 DAP formed another subgroup, suggesting they mark the period forming the main cell types and maturation of endosperm, respectively (Fig. 3C). The two subgroups form a larger cluster for active accumulation of storage compounds during 10 to 34 DAP. The distinct cluster of 36 and 38 DAP is in accordance with the end of storage compound accumulation in the endosperm and the activation of biological processes involved in dormancy and dehydration. In whole seed tissue, a primary cluster was formed from the earliest time points with 0 to 4 and 6 to 8 DAP samples as subgroups, separating the nucellus degradation, endosperm syncytial and cellularization phases from the rapid expansion of the endosperm and development of embryonic tissues (Fig. 3D). After 10 DAP, the embryo and endosperm dominate the formation of seed, as shown in figure 1 and morphological observation (Pennington et al., 2008). As effected by both embryo and endosperm, 10 to 28 DAP whole seed samples clustered together and 30 to 38 DAP formed another group (Fig. 3D). These results confirm that the expression data successfully captured the characteristic seed development phases and should therefore contain valuable insights about corresponding changes in the transcriptome.

**Integration of Gene Activity and Cellular Function across Development Phases**

The PCA and hierarchical clustering analysis graphically display the relationship among different samples, but do not indicate the detailed cellular function. Using the K-Means clustering algorithm, we classified the detected genes into 16, 14 and 10 coexpression modules for embryo, endosperm and whole seed respectively, each of which contains genes that harbor similar expression patterns (Fig. 4). We then used MapMan annotation to assign genes to functional categories (Supplemental Fig. S3).
Thus, we can aggregate genes over continuous time points and obtain a view of functional transitions along seed development.

According to the cluster analysis results, most modules of the embryo can be divided into middle (10–20 DAP) and late (22–38 DAP) stages (Fig. 4A). The middle stage, best represented by modules C1 to C7, is typified by the overrepresentation of glycolysis, tricarboxylic acid (TCA) cycle, mitochondrial electron transport, redox, RNA regulation, DNA and protein synthesis, cell organization and division related genes. This is consistent with the high requirement of energy during embryo formation. The late stage represented by C8 to C12, exhibited up-regulation of cell wall, hormone metabolism (ethylene, jasmonate), stress, storage proteins and transport related genes, which coincides with the maturation of the embryo. The modules C13 to C16 included genes that were broadly expressed across the time points sampled and were related to hormone metabolism (brassinosteroid), cold stress, RNA processing and regulation, amino acid activation and protein targeting.

All the 14 coexpression modules of endosperm can be roughly divided into early (6–8 DAP), middle (10–34 DAP), and late (36–38 DAP) stages (Fig. 4B). The early stage, represented by modules C1 to C4, is exemplified by high expression of hormone metabolism (gibberelin), cell wall, cell organization and cycle, amino acid metabolism, DNA and protein synthesis related genes, which is consistent with differentiation, mitosis and endoreduplication. Genes in the TCA cycle and mitochondrial electron transport are also overrepresented and related to energy demands at that time. The middle stage, best represented by C5 to C8, where different modules have distinct profiles, is the active storage accumulation phase and exhibits high expression of carbohydrate metabolism genes, as expected. Increased expression of protein degradation related genes around 26 to 34 DAP in C7 and C8 coincides with the process of endosperm maturation. Genes involved in protein degradation, secondary metabolism, oxidative pentose phosphate, receptor kinases signaling and transport were up-regulated in the late stage in modules of C9 to C14 during the concluding phase of endosperm maturation.

Ten DAP and later time points of whole seed samples reflect the additive
combination of embryo and endosperm expression. Genes that are active early in
development (0-8 DAP) in clusters C1 to C4 are expected to be related to maternal
tissue, which is the bulk of the seed at that time. A group of genes are highly
expressed in C1 at 0 DAP, but their expression drops rapidly by 2 DAP, suggesting
they have functional roles that precede pollination. This group includes
photosynthesis light reaction members and some TFs involved in RNA regulation.
Genes related to cell wall and protein degradation, signaling, nucleotide metabolism,
DNA synthesis, cell organization and mitochondrial electron transport are
overrepresented in C2 to C4, which has increased expression after pollination, in
accordance with the degradation of nucellus tissue and development of embryonic
tissues. The expression patterns and functional categories of the 1,506 genes detected
only in whole seed samples are shown in Supplemental Figure S4. Since these genes
tend to be expressed at high levels mainly before 8 DAP, they are presumed to have
functions in early seed development.

Together, these data show that the transition of major biochemical processes along
the developmental time axis of the seed is produced partly by highly coordinated
transcript dynamics.

TF Expression during Seed Development

Of the 2,297 identified maize TFs (Zhang et al., 2011), 1,614 (70%) are included in
our analysis (Supplemental Data Set S3), which accounts for 6.18% of the total
number of genes detected in seed tissue. The number of TFs detected in the different
samples is shown in Supplemental Figure S5A. Their proportion to the total genes
expressed in each tissue-time point was always greater in embryo than endosperm
samples (Supplemental Fig. S5B). Shannon entropy has been used to determine the
specificity of gene expression, with lower values indicating a more time-specific
profile (Makarevitch et al., 2013). The Shannon entropy of TFs was significantly
lower than all other genes in both embryo \( P = 2.3 \times 10^{-10} \) and endosperm \( P < 1.5 \times
10^{-3} \) indicating that TFs tended to be expressed more time-specifically than other
genes (Supplemental Fig. S5, C and D).

The number of TFs from each family used in the seed development program, along
with the proportion of members present in the coexpression modules relative to the total members of the family expressed in the tissue is shown in Supplemental Fig. S6. Enrichment of these TF families in the coexpression modules based on observed numbers was evaluated with Fisher’s exact test. Significant TF family enrichment was identified for specific coexpression modules. For example, 12 auxin-response factors (ARF) TFs (38.7%) were expressed in embryo module C2 during morphogenesis and half of the detected members of the WRKY family were active in endosperm module C12 late in endosperm development. The WRKY family has been reported to be mainly involved in the physiological programs of pathogen defense and senescence (Eulgem et al., 2000; Pandey and Somssich, 2009). Twenty-one MIKC family TFs (56.8%) were present in whole seed module C2, implying an important role in regulating genes involved in response to fertilization. The developmental specificity of the detected transcription factors makes them excellent candidates for reverse genetics approaches to investigate their role in grain production.

**Tissue-specific Genes of Seed**

Identification of uncharacterized tissue-specific genes can help to explain their function and understand the underlying control of tissue or organ identity. To generate a comprehensive catalogue of seed-specific genes, results from this study were compared to 25 published non-seed RNA-seq datasets (Jia et al., 2009; Wang et al., 2009; Li et al., 2010; Davidson et al., 2011; Bolduc et al., 2012), including root, shoot, SAM, leaf, cob, tassel and immature ear (Supplemental Table S2). In total, we identified 1,258 seed-specific genes, including 91 TFs from a variety of families (Supplemental Data Set S4). To gain further insight into the spatial expression trend in the developing seed, we divided these genes into four groups: embryo-specific, endosperm-specific, expressed in both embryo and endosperm, and ‘other’ as only expressed in whole seed (Table 1). The dynamic expression patterns of these genes reflect their roles in corresponding development stages (Supplemental Fig. S7). The largest numbers of seed-specific genes were observed in the endosperm, consistent with a study in maize using microarrays (Sekhon et al., 2011), perhaps reflecting the specific function of endosperm.
We compared the distribution of tissue-specific genes and TFs in embryo and endosperm coexpression modules to identify important phases in the underlying transcription network. Coexpression modules with an enrichment of tissue-specific genes or TFs may provide insight about uncharacterized genes and preparation for subsequent developmental processes. A feature of gene activity is shown in Figure 5. Fisher’s exact test ($P < 0.05$) was used to determine modules with significant enrichment of tissue-specific genes and TFs in the embryo and endosperm. In the embryo, TFs and tissue-specific genes were significantly enriched in the late phase, suggesting a specific process during maturation. In the endosperm, we observed that TFs and tissue-specific genes were overrepresented in the middle phase, which conforms to the role of endosperm in storage compound accumulation and to specific progress at this phase.

To gain further insight into the functional significance of tissue-specific genes, overrepresented GO terms were examined using the WEGO online tool (Ye et al., 2006) (Supplemental Fig. S8). All overrepresented GO terms were observed for the middle embryo development phase, including biosynthetic process, cellular metabolic process, macromolecule and nitrogen compound metabolic process. Similarly, overrepresented GO terms for the endosperm were mostly observed in the early phase, including macromolecule, nitrogen compound metabolic process, DNA binding, and transcription regulator. Genes involved in the nutrient reservoir class were enriched in the middle phase. The ‘oxidoreductase’ class was overrepresented in late phase, and is known to be involved in maturation (Zhu and Scandalios, 1994).

**The Expression of Zein Genes in Endosperm**

Zeins are the most important storage proteins in maize endosperm and are an important factor in seed quality. According to Xu and Messing (Xu and Messing, 2008), there are 41 alpha, 1 beta, 3 gamma and 2 delta zein genes. In order to explore their expression pattern, we first confirmed the gene models by mapping publicly available full length cDNAs of zein subfamily genes to B73 BACs, and then mapped these back to the reference genome. Because some of these zein genes were not assembled in the current B73 reference genome or were only annotated in the working
gene set, we confirmed a final set of 35 zein genes in the FGS of the B73 annotation, including 30 alpha, 1 beta, 3 gamma, and 1 delta zein genes (Supplemental Table S3). About three-quarters (26) of these were in the list of the 100 most highly expressed genes in the endosperm, based on mean expression across all endosperm samples (Supplemental Table S4). The distribution of these most highly expressed genes clearly showed that the 26 zeins and 4 starch synthesis genes were actively expressed in the middle phase of endosperm development, characteristic of storage compound accumulation (Fig. 6A).

Previous research has shown that the zein genes constitute 40% ~ 50% of the total transcripts in the endosperm (Marks et al., 1985; Woo et al., 2001), but these results are based on EST data from a single tissue or pooled tissues and only a few zein genes were assessed. Thus, we reevaluated the transcriptomic contribution of zein genes across endosperm development using our RNA-seq data, which is able to overcome the high structural similarity among them, especially in the alpha family (Xu and Messing, 2008). Zein genes stably accounted for about 65% of transcripts from 10 to 34 DAP, with 19-kD α-zeins (~ 42%), 22-kD α-zeins (~ 8%) and γ-zeins (~ 10%) representing the most abundant transcripts (Fig. 6B). The expression of different members within a given family was highly variable (Fig. 6C). Three genes contributed over 76% expression of the entire z1A family, and five genes accounted for about 98% expression of the z1C family. Expression of z1B and z1D families was almost entirely derived from two genes (Supplemental Table S3). All of the highly expressed genes appear to have intact coding regions as reported by Feng et al. (2009). However, we also detected expression of genes with a premature stop codon, and the expression level of these truncated zein genes is actually much higher than other non-zein genes (Supplemental Fig. S9).

It has been reported in rice that CpG and CHG hypomethylation is a major mechanism for the activation of genes in the endosperm (Zemach et al., 2010). To get a global view of the relationship between DNA methylation in gene body regions and the expression of genes in maize endosperm, we compared the RNA-seq data with recently published MethylC-seq data on the DNA methylation levels of B73 shoot, 12
DAP embryo and endosperm in CpG and CHG contexts (Zhang et al., 2013). We found that for endosperm-specific genes, there is a significant enrichment of differentially methylated regions (DMRs). These DMRs are hypomethylated in the endosperm compared with shoot and embryo tissue, regardless of CpG or CHG context (Supplemental Table S5). Of the zein genes, which were all expressed specifically in the endosperm, 31 harbored a hypomethylation state in the CHG context, 22 harbored a hypomethylation state in the CpG context, and 21 harbored a hypomethylation state in both CpG and CHG contexts (Supplemental Table S3). Three zein genes without associated DMRs seem to be an exception. Nevertheless, among these three, the 16-kD gamma zein (GRMZM2G060429) and 15-kD beta zein (GRMZM2G086294) were still hypomethylated, while a Z1B zein (GRMZM2G025763) was hypermethylated in all three tissues studied. Thus, we predict that gene body hypomethylation should have an important effect on activating the expression of genes in the endosperm, including zein genes.

**DISCUSSION**

We constructed a high resolution transcriptome atlas of maize seed development, using time series samples of embryo, endosperm and whole seed from fertilization to maturity. Our results show that at least 26,105 genes, including 1,614 TFs, are required to program maize seed development, which involves about 65.7 % of the B73 FGS genes. Global comparisons of gene expression highlighted the fundamental transcriptomic reprogramming and well demonstrated development phases present in embryo, endosperm and whole seed. Coexpression analysis illustrates the dynamic reprogramming of the transcriptome during maturation and reveals the functional transitions that take place during seed development. Combined with published non-seed RNA-seq data, we identified 1,258 seed development specific genes, including 91 TFs, which should facilitate the identification of functional processes and regulatory networks that are important for programming seed development. Although very early embryo and endosperm tissues were not available due to the difficulty in manual sample collection, our data serve as a valuable resource for the in-depth understanding of the dynamics of gene expression throughout maize seed
Expression Patterns Imply Gene Function and Inform Cellular Processes

The development of seed is highly complex and requires a vast interaction of genes and cooperation of processes. Confirming the phases of different processes has an important significance in expounding seed development and guiding the selection of tissue development stages for different purposes. Many seed development studies have been previously performed from the perspective of morphology, storage accumulation and gene expression (Kiesselbach, 1949; Woo et al., 2001; Lee et al., 2002; Liu et al., 2008), but the deep profiling in this study fills in many missing details.

Although embryo and endosperm samples were well distinguished, common variance in expression was observed over the stages of development by PCA (Fig. 3A) and expression of genes present in both embryo and endosperm tended to be positively correlated (Supplemental Fig. S10), indicating large sets of genes change coordinately in the embryo and endosperm over development. It is reasonable to assume that there are some regulators shared between embryo and endosperm, so that the two relatively independent seed tissues can proceed and complete the development process at the same time. In Arabidopsis, a global comparison of mRNA populations also suggested that substantial coordination of biological processes occurs in embryo and endosperm regions (Belmonte et al., 2013). However, the regulators responsible for coordinating the embryo and endosperm development remain to be determined.

Starch constitutes most of the biomass of the mature modern maize hybrid and is the main yield component being improved by breeding. Starch biosynthesis requires the coordinated activities of several enzymes, for which different isozymes have different effects (Jeon et al., 2010). The major form of sucrose synthase (SUS) and granule-bound starch synthase (GBSS) in the endosperm is encoded by Sh1 and Waxy1 (WxI) respectively (Carlson and Chourey, 1996; Vrinten and Nakamura, 2000). These can be revealed by the expression of Sh1 and WxI and they account for almost all of the transcripts of SUS and GBSS respectively (Supplemental Fig. S11). Our
results are also consistent with earlier studies that three of the eight soluble starch synthase (SS) paralogs (SsI, SSIIa, DuI), two of the four starch branching enzyme (SBE) paralogs (SbeI, SBEIIb), and two of the four starch debranching enzyme (DBE) paralogs (SuI, ZpuI) play a major role in starch synthesis (Yun and Matheson, 1993; Beatty et al., 1999; Cao et al., 1999; Ball and Morell, 2003; Zhang et al., 2004; Fujita et al., 2006). Except for ZpuI, all of these main genes are members of two similar endosperm coexpression modules (C5 and C6), as well as Brittle2 (Bt2) and Shrunken2 (Sh2), two key enzymes in starch synthesis (Ballicora et al., 2004). Genes functioning in the same pathway tend to appear in the same or similar expression modules, indicating that the coexpression data provides excellent inferences for uncharacterized genes through ‘guilt by association’. For example, the maize orthologs of flo2 and flo4 in rice belong to module C6 and C5 of the endosperm, respectively, which indicates they may function in starch accumulation similar to rice (Kang et al., 2005; She et al., 2010).

Roles of Seed-specific Genes

About 4.8% (1,258) of the total genes detected during seed development were identified as seed-specific genes, which are more than the number reported by Sekhon et al. (2011), due to the RNA-seq technology and more extensive sampling in our study. In rice, Wang et al. (2010) predicted 589 seed-specific genes, 411 of which can be identified in the Nipponbare reference genome. According to the maizeGDB, 155 of them have orthologs in maize, nearly half of which (68) were found to have seed-specific ortholog genes in maize. This result suggests high conservation between rice and maize in whether a gene is specifically expressed in the seed ($P < 2.2 \times 10^{-16}$), even though different methods of calculating gene expression and different criteria were used to determine the tissue-specificity.

The functions these specific genes play in seed development is a critical question. Previous genetic studies with seed defective mutants have demonstrated the functional significance of certain seed-specific genes. For example, VpI and LEC1 are important for embryogenesis and maturation (McCarty et al., 1991; Lotan et al., 1998). Other examples include O2, Sh2, BtI and Bt2, which are involved in storage compound
accumulation (Russell et al., 1993; Vicente-Carbajosa et al., 1997; Shannon et al., 1998), Fie1 and Meg1, two endosperm imprinting genes (Gutiérrez-Marcos et al., 2004; Raissig et al., 2011), Glb1 and Glb2, two embryo storage protein genes (Kriz, 1989), and Floury2, a zein gene in the endosperm (Fontes et al., 1991). Such well-studied genes represent a small proportion of the 1,258 identified seed-specific genes, but this study provides information on when all these genes are actively expressed (Supplemental Fig. S7). The timing of seed-specific gene expression in development combined with predictions of gene function based on their annotation (Supplemental Fig. S8) is very useful for accelerating understanding of their role.

Potential Mechanisms in Endosperm for Extremely High Expression of Zein Genes

Of the 100 most highly expressed genes in the endosperm, 54 genes fall into expression modules in the middle phase of endosperm development. Among these highly expressed genes, the zeins collectively account for about 65% of the total endosperm transcripts, consistent with previous observations (Marks et al., 1985; Woo et al., 2001). Therefore, there must be some mechanisms in the endosperm which allow the rapid and drastic increase in the expression level of particular genes. One possible mechanism is to increase the metabolic capacity of the endosperm by endoreduplication with a large-scale increase in the amount of transcriptional templates to support high transcription rates (Sugimoto-Shirasu and Roberts, 2003). Based on our data, although storage accumulation is the longest phase of endosperm development, only 16.3% (3,654) of genes were actively expressed during this stage and a large number of genes are actually down-regulated (Fig. 2C and 4B). Thus, we propose that there is an active mechanism in the endosperm to limit a number of metabolic processes to save resources for the synthesis and accumulation of storage compounds in this special period. In addition, the excessive ‘overdraft’ to perform such a specific function of storage accumulation over such a long time for seed filling may be a reason that the starchy endosperm cells undergo PCD prior to desiccation and quiescence (Young and Gallie, 2000, 2000). In contrast, there is little accumulation of zein proteins in aleurone cells (Reyes et al., 2011), consistent with
the fact that the aleurone cells do not undergo PCD until germination (Fath et al., 2000).

Despite the importance of zein protein accumulation in the endosperm, the mechanisms by which these genes are regulated are still not clear. Previous studies have shown that DNA methylation status may be an important factor. For example, a recent study demonstrated that the promoter regions of zein genes have different methylation patterns with differences between tissues (Miclaus et al., 2011). The low methylation level in these promoters is not a result of $O_2$ regulation (Locatelli et al., 2009). The gene bodies of storage protein genes were also found to be undermethylated in the endosperm when compared to other tissues (Bianchi and Viotti, 1988). Our study extends the analysis to gene bodies of all the zein genes and shows that the high expression of zein genes in endosperm is highly correlated with DNA hypomethylation in gene body, which is consistent with a recent study in rice (Zemach et al., 2010). Therefore, gene body hypomethylation seems to be a common mechanism for activating the expression of endosperm-specific genes.

MATERIALS AND METHODS

Plant Material and Sequencing

The maize (*Zea mays*) inbred line B73 was grown in the field in the summer of 2012 in Beijing, China. Ears were self-pollinated on the same day. All samples of embryo, endosperm and whole seed were collected by manual dissection and frozen immediately in liquid nitrogen, and stored at -80°C before processing. Each sample was obtained from at least three plants.

Total RNA was extracted using TRIzol reagent (Invitrogen). RNA-seq libraries were prepared according the manufacturer’s protocol of Illumina Standard mRNA-seq library preparation kit (Illumina USA) and were sequenced to generate 101nt paired-end reads on Illumina HiSeq platform.

Read Mapping and Gene Expression Analysis

The raw reads were aligned to the B73 reference genome (RefGen_v2) using
Tophat 2.0.6 (http://tophat.cbcb.umd.edu/) (Trapnell et al., 2009) with maximum intron length set to 30 kb, with default settings for other parameters. We calculated the number of uniquely mapped reads for each gene model in the B73 FGS by parsing the alignment output files from Tophat, and then normalized the resulting read counts by RPKM (reads per kilobase per million mapped reads) to measure gene expression level. We calculated the Pearson correlation coefficient between biological replicates with R using genes expressed in at least one of the samples. Maize reference genome sequence data and the FGS 5b were downloaded at http://maizesequence.org.

Principal Component Analysis and Hierarchical Clustering

To facilitate graphical interpretation of relatedness among 53 different seed samples, we reduced the dimensional expression data to two dimensions by PCA using the prcomp function in R with default settings (R Development Core Team, 2012). Hierarchical clustering was performed by pvclust package with default settings using Pearson’s correlation distance (Suzuki and Shimodaira, 2006). The transformed and normalized gene expression values with log 2 (RPKM + 1) were used for the analysis of PCA and hierarchical clustering.

Gene Coexpression Analysis

We conducted the coexpression analysis for embryo, endosperm and whole seed, respectively, using MeV, which was downloaded from http://www.tm4.org/mev.html. Before running the MeV for a tissue, we calculated the relative expression values of the genes by dividing their expression level at different time points with their maximum observed RPKM. The relative expression levels were used as input for MeV and clustered using the k-means method and Pearson correlation coefficients among the genes. The figure of merit (FOM) (Yeung et al., 2001) was used to determine the optimal cluster number. Functional category enrichment for each cluster was evaluated with the MapMan annotation (Thimm et al., 2004). Before conducting MapMan annotation, the longest protein of each FGS gene was chosen as a representative protein and the Mercator was run with default settings. Over and under representation of functional categories in a cluster were determined with Fisher’s exact test. Resulting P-values were adjusted to Q-values by Benjamini-Hochberg.
correction, and an FDR of 5% was applied.

Identification of Seed-specific Gene Expression

To identify genes that are preferentially expressed in seed tissues, we downloaded 25 non-seed RNA-seq datasets (Supplemental Table S2) from NCBI (http://www.ncbi.nlm.nih.gov/) and calculated gene expression level. We then used the Z-score value to determine whether a gene expressed specificity in seed. The expression across all the samples was normalized using \( \log_2 (RPKM + 0.01) \). For a given gene, we calculated Z-scores of the gene in different seed samples by compared with the non-seed sample dataset using the normalized expression level. The gene was determined to be seed-specific expressed if it has a Z-score above 3 in at least one of seed samples.

Then, we divided the identified seed-specific genes into different parts (Table 1). We found 45 genes that were not expressed in any of the embryo or endosperm samples, but present in whole seed samples, so they were classified as ‘other’. The remained seed-specific genes were further determined if they were specific expressed in embryo or endosperm. The Z-score value was used as identifying seed-specific genes, the difference is that raw RPKM value was used instead of the \( \log_2 \) transformed. A gene was determined to be ‘embryo-specific’ if it has a Z-score above 3 in at least one of embryo samples when compared with endosperm samples. Similarly, a gene was determined to be ‘endosperm-specific’ if it has a Z-score above 3 in at least one of endosperm samples when compared with embryo samples. In addition, genes were considered to have expression in both embryo and endosperm if they could not be classified as embryo or endosperm-specific.

Identification of DMRs

The DMRs among embryo (12 DAP), endosperm (12 DAP) and shoot tissue were identified as described in our previous study (Zhang et al., 2013) with some modifications. Briefly, MethylC-seq reads were first processed by SolexaQA software (Cox et al., 2010) to filter out low quality bases (< 13). Next, processed reads were aligned to the B73 reference genome (RefGen_v2) using Bismark (Krueger and Andrews, 2011). Only uniquely mapped reads were used to determine methylation
level. When identifying DMRs, we applied a sliding-window approach to overcome
the limit of sequencing depth with window size of 200 bp and slide step of 100 bp
across the whole genome. Windows that contain more than five CGs/CHGs and
supported with at least five reads were kept. Fisher’s exact test was used to weight the
significance of differentially methylated regions, and resulting P-values were adjusted
to Q-values. Regions with Q-value \( \leq 0.01 \) and methylation level differences of more
than 30% between two samples were determined to be DMRs, and overlapping DMRs
within 200 bp were merged. For CG context, the hypermethylated sample was also
required to have methylation levels of more than 40% to be considered a DMR.

**Supplemental Data**
The following materials are available in the online version of this article.

- **Supplemental Figure S1.** Correlation between biological replicates.
- **Supplemental Figure S2.** Expression profiles of *LEC1, Glb2, Fie1* and *O2* in the
  53 samples.
- **Supplemental Figure S3.** MapMan functional categories enriched in different
  coexpression modules of embryo, endosperm and whole seed.
- **Supplemental Figure S4.** Expression patterns and MapMan functional categories
  of the 1,506 genes only detected expression in the whole seed samples.
- **Supplemental Figure S5.** Analysis of TF expression across samples.
- **Supplemental Figure S6.** TF distribution in the embryo, endosperm and whole
  seed coexpression modules.
- **Supplemental Figure S7.** Expression patterns of seed-specific genes in all seed and
  non-seed Samples.
- **Supplemental Figure S8.** WEGO annotation of embryo and endosperm specific
genes.
- **Supplemental Figure S9.** Comparison of expression levels of different gene types
in endosperm.

**Supplemental Figure S10.** Distribution of coexpression between embryo and endosperm samples.

**Supplemental Figure S11.** Genes involved in starch biosynthesis pathway.

**Supplemental Table S1.** Summary of RNA-Seq read mapping results.

**Supplemental Table S2.** List of published non-seed RNA-seq data used to find seed-specific genes.

**Supplemental Table S3.** Summary of zein genes detected in B73.

**Supplemental Table S4.** List of the 100 most highly expressed genes in endosperm shown in Figure 6A.

**Supplemental Table S5.** Summary of DMR among embryo, endosperm and shoot samples.

**Supplemental Data Set S1.** Expression level of FGS genes in different samples.

**Supplemental Data Set S2.** Number of genes and TFs detected in different seed samples.

**Supplemental Data Set S3.** List of TFs expressed in seed samples.

**Supplemental Data Set S4.** Summary of different types of seed-specific genes shown in Table 1.
