Abstract

Several members of the AGCVIII kinase subfamily that includes PINOID (PID), PID2 and WAG proteins have previously been shown to phosphorylate PIN-FORMED (PIN) auxin transporters and control the auxin flow in plants. PID has been proposed as a key component of the phototropin (phot) signaling pathway that induces phototropic responses, although the responses were not significantly impaired in the pid single and pid wag1 wag2 triple mutants. This raises questions about the functional roles of the PID family in phototropic responses. Here, we investigated hypocotyl phototropism in the pid pid2 wag1 wag2 quadruple mutant in detail to clarify the roles of the PID family in Arabidopsis. The pid quadruple mutants exhibited moderate responses in continuous-light-induced phototropism with a decrease in growth rates of hypocotyls and normal responses in pulse-induced phototropism. On the other hand, it showed serious defects in enhancements of pulse-induced phototropic curvatures and lateral fluorescent auxin transport by red light pretreatment. Red light pretreatment significantly reduced the expression level of PID, and the constitutive expression of PID prevented pulse-induced phototropism irrespective of red light pretreatment. This suggests that the PID family plays a significant role in phytochrome-mediated phototropic enhancement, but not in the phot signaling pathway. Red light treatment enhanced the intracellular accumulation of PIN proteins in response to the vesicle-trafficking inhibitor brefeldin A, in addition to an increase of their expression levels. Taken together, these results suggest that red light preirradiation enhances phototropic curvatures by upregulation of PIN proteins, which are not being phosphorylated by the PID family.
Sessile organisms such as plants develop many adaptational mechanisms. Phototropism is one such acclimation response in plants to light environments, by which they can advantageously obtain light energy for photosynthesis. So far, phototropic responses, which have been well studied for many years, are separated mainly into two types according to their characters: the first positive phototropism and the second positive phototropism (Iino, 2001; Whippo and Hangarter, 2006; Briggs, 2014). The first positive phototropism is induced by a pulse of blue light and the magnitudes of the responses are dependent totally on the total light fluence. On the other hand, the second positive phototropism is induced by a prolonged irradiation of blue light, and the extent of the curvature responses depends upon the duration of the blue light illumination, not on the total light fluences.

Classical physiological analysis has revealed that plant photoreceptor phytochromes influence phototropin (phot)-mediated phototropic responses in several aspects (Iino, 2001; Whippo and Hangarter, 2006; Sakai and Haga, 2012; Briggs, 2014). For the first positive pulse-induced phototropism, phytochromes are involved in the enhancement of phototropic curvatures in addition to desensitization (Liu and Iino, 1996a; Janoudi et al., 1997a; Whippo and Hangarter, 2004; Haga and Sakai, 2012). For the second positive phototropism, phytochromes participate in the establishment of a phototropic system, which is necessary to respond to a prolonged irradiation of blue light, in the promotion of phototropic curvature rates, and in the reduction of the time required to induce curvature responses (Janoudi et al., 1992; Liu and Iino, 1996b; Hangarter, 1997; Haga and Sakai, 2012). All such regulation is controlled by multiple phytochromes (Parks et al., 1996; Hangarter, 1997; Janoudi et al., 1997a, 1997b; Whippo and Hangarter, 2004). However, the molecular mechanisms underlying the phytochrome-mediated regulation of phototropism remain largely unknown (Briggs, 2014).

Recent studies indicate that red light treatment, which activates phytochrome, induces several cellular events related to phototropic enhancement. Han et al. (2008) reported that red light pretreatment inhibits the blue-light-dependent loss of phot1 from the plasma membrane. Nagashima et al. (2008a) demonstrated
that red light irradiation reduces the expression of ATP-BINDING CASSETTE subfamily B19 (ABCB19), which is an auxin efflux transporter known to be a negative regulator for phototropism (Noh et al., 2003; Nagashima et al., 2008b). Furthermore, ABCB19 is directly phosphorylated by phot1, resulting in the reduction of auxin transport (Christie et al., 2011). Kami et al. (2012) showed that the red-light-induced nuclear import of phytochrome A is necessary for the acceleration of phototropic curvature rates by red light pretreatment in continuous-light-induced phototropism. Although these cellular events may be required to establish phototropic enhancement, how they are associated with the enhancement has not been elucidated.

The PINOID (PID) family belongs to the AGC kinase family and consists of four members (PID, WAG1, WAG2, and PID2) in Arabidopsis (Galván-Ampudia and Offringa, 2007). The PID family is known to be involved in the localization of auxin efflux carrier PIN-FORMED (PIN) proteins (Friml et al., 2004; Michniewicz et al., 2007; Huang et al., 2010). However, the functions of PID2 have not been well elucidated. Careful analysis with the pid single mutant demonstrated that PID is partially involved in both the pulse-induced first positive phototropism and the time-dependent second positive phototropism (Haga and Sakai, 2012). Furthermore, the pid wag1 wag2 triple mutant showed partial impairment of the continuous-light-induced second positive phototropism (Ding et al., 2011; Preuten et al., 2013). Therefore, the PID family appeared to be one of the key components for the regulation of phototropic responses.

Recently, it was proposed that phot-mediated transcriptional downregulation of PID is involved in the asymmetrical distribution of PIN3 during continuous-light-induced phototropism (Ding et al., 2011). On the other hand, it was reported that transcriptional downregulation of the PID family is also induced by overhead red light treatment (Haga and Sakai, 2012). Furthermore, we also demonstrated that PID participates in the phytochrome-mediated regulation of phototropism, because the pid single mutant showed partial impairment of phototropic enhancement by red light pretreatment (Haga and Sakai, 2012). Therefore, it is possible that the PID family functions not only in the
phot-mediated regulation of the localization of PIN proteins but also in the phytochrome-mediated regulation of phototropism.

In this study, we investigated hypocotyl phototropism in the pid quadruple mutant, which had not been used for phototropic analysis, using a precise physiological method (Haga and Sakai, 2012) to elucidate the physiological functions of the PID family in phototropic responses. Intriguingly, phytochrome-mediated phototropic enhancement was severely impaired in the pid quadruple mutant, indicating that the PID family is a critical component for phytochrome regulation. In addition, our analysis suggests that the PID family is not necessary for continuous-light-induced phototropism because the pid quadruple mutant showed nearly normal phototropism when induced by continuous blue light irradiation.
RESULTS

The PID Family Is Not Necessary for Continuous-Light-Induced Second Positive Phototropism

To examine a functional redundancy among the PID family members in hypocotyl phototropism of Arabidopsis, we prepared the pid pid2 wag1 wag2 quadruple mutant by crossing pid-14 (Salk_049736) with wag1 (Salk_002056C), wag2 (Salk_070240), and pid2 (Sail_269_G07) mutants. The genetic combination of the pid quadruple mutant we generated was the same as that produced by Chen et al. (2008). The pid quadruple mutant lacked cotyledons, as reported previously (Chen et al., 2008), but showed the apical hook formation under darkness and the hook opening under overhead white light without cotyledons (Fig. 1A). First, we investigated continuous-light-induced second positive phototropism in the pid quadruple mutant by using two different fluence rates of blue light: very low (0.0017 \( \mu \text{mol m}^{-2} \text{s}^{-1} \)) and low (0.17 \( \mu \text{mol m}^{-2} \text{s}^{-1} \)) (Fig. 1, B and C). Although the steady-state levels of phototropic curvatures of the mutant were similar to those of the wild type irrespective of fluence rates, curvature rates and the oscillation were slightly attenuated compared with the wild type (Fig. 1, B and C). The mutant showed a decrease of the hypocotyl growth rates (Fig. 1D), suggesting that its reduction is involved in the attenuation of phototropic curvature rates in the pid quadruple mutant. Overhead red light pretreatment for 2 min before 2 h of the phototropic stimulation reduced the lag time to induce phototropic responses and accelerated phototropic curvature rates in wild-type hypocotyls (Fig. 1, B and C), as described previously (Hangarter, 1997; Haga and Sakai, 2012). Similar responses were also observed in the mutant (Fig. 1, B and C). These results indicated that the PID family does not play any significant role in continuous-light-induced hypocotyl phototropism.

The PID Family Is Necessary for Phytochrome-Mediated Enhancement of Pulse-Induced First Positive Phototropism

Next, we evaluated the roles of the PID family in pulse-induced first positive phototropism. Dark-grown seedlings were stimulated with unilateral blue light for
1 min at optimum total fluence (0.1 μmol m⁻²) and phototropic curvatures were determined 3 h after the onset of blue light irradiation (Haga and Sakai, 2012; Fig. 2A). Because oscillation responses observed in the continuous-light-induced phototropism (Fig. 1) were not induced by a pulse of blue light (Haga and Sakai, 2012), time-course analysis was not conducted for the pulse-induced phototropism. Wild-type seedlings showed phototropic curvatures of more than 20° and the pid quadruple mutant also exhibited similar phototropic curvatures (Fig. 2B, left panel). The effects of red light pretreatment were also examined in pulse-induced phototropism. Dark-grown seedlings were pretreated with overhead red light for 2 min before 2 h of the phototropic stimulation, and the hypocotyls were then stimulated with unilateral blue light for 1 min at optimum total fluence (1 μmol m⁻²). Although red light pretreatment enhanced phototropic responses in the wild type, the pid quadruple mutant did not show such phototropic enhancement (Fig. 2B, right panel). Although the previous study had already reported that the pid single mutant exhibits a reduction of red light effects on pulse-induced phototropism (Haga and Sakai, 2012), the pid quadruple mutant showed the more severe phenotype in this response.

To understand better the roles of the PID family in the enhancement of phototropic responses, we next analyzed the fluence-response relationship of pulse-induced phototropism with or without red light pretreatment (Fig. 2C). When red light pretreatment was not used, the fluence-response curve in the pid quadruple mutant was very similar to that in the wild type. It is known that red light pretreatment causes two major alterations of fluence-response curves: enhancement of phototropic curvatures and a shift in the optimum total fluence of blue light to higher fluences, so-called desensitization (Liu and Iino, 1996a; Haga and Sakai, 2012). Although the optimum total fluence was shifted to higher fluences of blue light in the pid quadruple mutant, the enhancement of phototropic curvatures was severely impaired in the mutant (Fig. 2C). Therefore, these results indicated that the PID family plays a significant role in phytochrome-mediated enhancement of pulse-induced phototropism, but not in the phot signaling pathway.
The PID Family Is Required for Phytochrome-Mediated Enhancement of Time-Dependent Second Positive Phototropism

We subsequently investigated time-dependent second positive phototropism (Fig. 3). Without red light pretreatment, phototropic curvatures deviated slightly from the fluence-response curve of pulse-induced phototropism following 27 min of irradiation, but not 9 min of irradiation, in the wild type (Fig. 3B). However, the red light pretreatment significantly promoted the deviation in phototropic responses, and 9 min of irradiation was enough for second positive phototropism to appear (Fig. 3C). The results indicated that red light pretreatment, presumably through phytochromes, is necessary for the induction of time-dependent phototropism as reported previously (Janoudi et al., 1992; Liu and Iino, 1996b; Haga and Sakai, 2012). The pid quadruple mutant showed obvious responses of time-dependent phototropism with red light pretreatment and no clear responses without red light pretreatment similar to the wild-type response, although the magnitudes of the curvature responses were partially impaired in the mutant (Fig. 3, B and C). Therefore, the results indicate that the PID family is necessary for amplification of time-dependent phototropic responses by red light pretreatment and that the occurrence of phototropic responses itself is independent of PID function.

Constitutive Expression of PID Attenuates Hypocotyl Phototropism

We also analyzed the effects of constitutive expression of PID on hypocotyl phototropism using transgenic plants harboring the cauliflower mosaic virus 35S promoter driven PID cDNA gene (35S::PID). Pulse-induced phototropism and time-dependent phototropism were severely impaired in the transgenic plants while continuous-light-induced phototropism was slightly attenuated (Fig. 4A). Time course analysis of continuous-light-induced phototropism indicated that phototropic curvature rates were reduced and oscillation responses were severely impaired in the transgenic plants, although the steady-state levels of phototropic curvatures were very similar to those of the wild type (Fig. 4B). The results suggest that excessive amounts of PID proteins prevent phototropic responses, especially pulse-induced and time-dependent phototropisms.
Phytochrome Reduces PID Protein Levels

Although the present study clearly demonstrated that the PID family has a critical role in phytochrome-mediated enhancement of phototropic responses, it remains unclear how PID kinases are involved in the enhancement. Because it has been reported that red light treatment reduces the transcriptional levels of PID genes in Arabidopsis hypocotyls (Haga and Sakai, 2012), such regulation may participate in the enhancement. To investigate this possibility, we examined the effects of red light pretreatment on the expression of PID using a yellow fluorescent protein VENUS (Fig. 5). When dark-grown transgenic plants harboring the VENUS-fused PID gene driven by its own promoter (PID::PID-VENUS) were not treated with overhead red light, the fluorescent signals derived from PID-VENUS were detected in cell peripheral regions of the epidermis around the apical shoots, but not in the hypocotyls (Fig. 5, A and B). This suggests that PID proteins are localized at the plasma membrane of epidermal cells, as described previously (Michniewicz et al., 2007; Kleine-Vehn et al., 2009), and that PID functions mainly in the apical parts at least in dark-grown seedlings. Therefore, we focused on the apical regions for further analysis. Red light treatment reduced the fluorescent signals significantly 2 h after the treatment (Fig. 5C), while clear attenuation was not observed at an earlier time, such as 15 min after the pretreatment (data not shown). The results support the previous view that transcriptional levels of PID are attenuated by red light irradiation (Haga and Sakai, 2012). This suggests that PID protein levels are also reduced through transcriptional downregulation of PID. Therefore, we concluded that a reduction of PID protein levels is probably involved in phytochrome-mediated phototropic enhancement.

Phytochrome Enhances Expression Levels of PIN Proteins

Previously, we reported that red light pretreatment enhances transcriptional levels of the PIN family (Haga and Sakai, 2012), suggesting that accumulation of PIN proteins are induced by the pretreatment. To investigate the possibility, we generated the transgenic pin3 and pin7 mutants harboring PIN3::PIN3-VENUS and PIN7::PIN7-VENUS (the VENUS-fused PIN gene driven by its own
promoter), respectively, and examined the effects of red light treatment (Fig. 6). When expression patterns of PIN-VENUS were observed around the apical hook regions where the expression level of PID-VENUS (Fig. 5) was relatively high, the light treatment enhanced the fluorescent signals derived from PIN-VENUS, and the enhancement was more significant in the pin7 transgenic plants harboring PIN7::PIN7-VENUS (Fig. 6A). The promotional effects were also observed in the hypocotyls just below the hook regions. On the other hand, both PIN3-VENUS and PIN7-VENUS did not show clear polarity and the red light treatment did not alter the distribution of the fluorescence (Fig. 6B). The results indicate that red light pretreatment enhances protein levels of the PIN family, while it does not affect the distribution of PIN proteins.

PIN proteins are known to undergo constitutive cycles of clathrin-mediated endocytosis and recycling to the plasma membrane via a brefeldin A (BFA)-sensitive exocytosis pathway or a BFA-independent pathway (Dhonukshe et al., 2007; Kleine-Vehn et al., 2009). BFA is a fungal toxin that inhibits a subset of guanine nucleotide exchange factors for ADP-ribosylation factors including GNOM, and its treatment inhibits PIN recycling and leads to PIN accumulation into so-called BFA compartments (Steinmann et al., 1999; Geldner et al., 2001). As the PID-dependent PIN phosphorylation decreases affinity of PIN proteins for the BFA-sensitive exocytosis pathway (Kleine-Vehn et al., 2009), downregulation of PID by red light pretreatment appeared to suppress the PID-dependent PIN phosphorylation and stimulate the PIN accumulation into BFA compartments under BFA treatment conditions. When dark-grown pin7 transgenic plants harboring PIN7::PIN7-VENUS were treated with the inhibitor, VENUS signals were mainly observed around cell peripheral regions, and intracellular BFA compartments were rarely observed (Fig. 6C). However, red light treatment enhanced the accumulation of PIN7-VENUS into BFA compartments significantly (Fig. 6C). Although it is possible that reduction of PIN proteins by red light treatment influences formation of BFA compartments, the results suggested that red light irradiation increases the population of PIN proteins, which are not being phosphorylated by PID and are recycled to the plasma membrane via a BFA-sensitive exocytosis pathway.
The PID Family Is Necessary for the Promotion of the Auxin Gradient During the Enhanced Pulse-Induced Phototropism

We also examined the distribution of auxin during pulse-induced phototropism in the *pid* quadruple mutant. Recently, a fluorescent auxin analog [7-nitro-2,1,3-benzoxadiazole (NBD)-conjugated naphthalene-1-acetic acid (NAA), NBD-NAA] has been developed to visualize auxin distribution (Hayashi et al., 2014). When dark-grown seedlings were treated with NBD-NAA, fluorescent signals were evenly distributed in the epidermis of hypocotyls of both the wild type and the *pid* quadruple mutant without phototropic stimulation (Fig. 7, A and B, left). When the seedlings were stimulated with a pulse of blue light at an optimum total fluence, fluorescent signals on the shaded side were stronger than those on the irradiated side in both the wild type and the mutant (Fig. 7, A and B, right). The uneven distribution of the fluorescent signals observed in the wild type was very similar to that in the wild type harboring *DR5rev::GFP*, as previously reported (Haga and Sakai, 2012). The results strongly suggested that gradients of the fluorescent signals reflect an asymmetrical distribution of auxin. On the other hand, red light pretreatment enhanced the uneven distribution of fluorescent signals in the wild type but not in the *pid* quadruple mutant (Fig. 7, C and D). The results suggest that phytochrome-mediated promotion of the auxin gradient is specifically impaired in the *pid* quadruple mutant.

DISCUSSION

It is well known that phytochrome affects many aspects of phot-mediated phototropic responses in plants. Major aspects of phytochrome regulation are phototropic adaptation and enhancement (Iino, 2001; Whippo and Hangarter, 2006; Briggs, 2014). Our previous study suggested the partial involvement of PID in the phytochrome-mediated enhancement of phototropism (Haga and Sakai, 2012). The present study extends the previous results, demonstrating that phototropic enhancement is dependent totally on the PID family, especially in pulse-induced first positive phototropism (Fig. 2). In addition, the promotive effect of red light pretreatment on the auxin gradient was severely impaired in the *pid* quadruple mutant (Fig. 7). It has been reported that PIN proteins are necessary
for the asymmetrical distribution of auxin during pulse-induced phototropism (Haga and Sakai, 2012). Furthermore, it is known that PID kinases regulate the functions of PIN proteins through changes in their phosphorylation status (Friml et al., 2004; Michniewicz et al., 2007; Huang et al., 2010). Therefore, it appears that the PID family is involved in phytochrome-mediated phototropic enhancement through regulation of the phosphorylation status of PIN proteins.

Red light treatment reduced the levels of PID proteins largely (Fig. 5) because of the transcriptional downregulation of the PID family (Haga and Sakai, 2012) although protein turnover may be also involved. On the other hand, red light enhanced the accumulation of PIN proteins into BFA compartments (Fig. 6C). Because it has been reported that nonphosphorylated PIN proteins are transported to the plasma membrane preferentially through a GNOM-dependent exocytosis pathway that is severely impaired by BFA treatment (Kleine-Vehn et al., 2009), it is most likely that reduced levels of PID proteins increase the population of nonphosphorylated PIN proteins when dark-grown seedlings are stimulated with red light. Therefore, it is possible that nonphosphorylated PIN proteins are more sensitive to the phot-mediated regulation of auxin transport activity and/or subcellular localization than phosphorylated PIN proteins (Fig. 8), resulting in enhancement of the auxin gradient. In addition, PID-mediated regulation of auxin transport activity of PIN proteins may be also involved in the enhancement of phototropic responses directly or indirectly, because a recent study has indicated that PID regulates not only the subcellular localization but also the auxin transport activity of PIN proteins (Zourelidou et al., 2014). It should be noted, however, that both of the pid quadruple mutant and the PID overexpression line exhibit an impairment of phototropic curvatures. It suggests that the PID family not only negatively but also positively functions in the phototropic responses. The balance of PID levels and/or function of PID under darkness may be necessary for expression of the phytochrome-mediated phototropic enhancement.

Because red light treatment enhanced protein levels of the PIN family (Fig. 6), phytochrome-mediated phototropic enhancement may result from the promotion of PIN activity through transcriptional upregulation of the PIN family (Haga and
Sakai, 2012) in addition to the emergence of greater asymmetry of PIN activity and/or localization by downregulation of the PID family (Fig. 8). Because it is reported that PID functions as a negative regulator for auxin transport activity of PIN proteins interacting with ABCB1 proteins (Wang et al., 2012), it appears that such a regulatory mechanism also participates in phototropic enhancement. Further studies are necessary to clarify the molecular mechanisms underlying phytochrome-mediated phototropic enhancement.

The present study indicates that the PID family is not required for phytochrome-mediated phototropic adaptation (desensitization). Our previous study suggested that ROOT PHOTOTROPISM 2 (RPT2), a phot adaptor protein, is the most likely candidate for photosensory adaptation in phototropic responses (Fig. 8; Sakai et al., 2000). This is because the rpt2 mutant is responding to a very limited range of light fluence rates, and the transcriptional levels of RPT2 are upregulated by light treatment (Sakai et al., 2000). On the other hand, it has been proposed that phytochrome-mediated stabilization of the membrane localization of phot is involved in phytochrome-mediated phototropic regulation. This is because red light pretreatment prevents blue-light-induced internalization of phot proteins from the plasma membrane (Han et al., 2008). However, blue light irradiation at lower fluences, which is still effective in inducing hypocotyl phototropism in Arabidopsis, could not attenuate the membrane localization of phot proteins significantly (Supplemental Fig. S1). Therefore, it appears that phytochrome-mediated stabilization of phot membrane localization functions in phototropic responses induced by higher intensities of blue light (e.g. 20 μmol m⁻² s⁻¹), but not by lower intensities of the light.

In dark-grown seedlings, PID proteins were mainly localized at the epidermal cell peripheral region of shoot apical parts (Fig. 5). Very recently, it has been reported that the upper parts of Arabidopsis shoots are very important for the perception of phototropic signals and in the production of auxin asymmetrical distribution (Preuten et al., 2013; Yamamoto et al., 2014). Furthermore, severe impairment of phototropic responses in the phot1 mutant was complemented by the expression of phot1 in epidermal cells (Preuten et al., 2013). Taken together
with the present study, critical events involved in hypocotyl phototropism may occur at the most apical epidermal cells in Arabidopsis.

The *pid* quadruple mutant showed that its apical hook opens slightly when 2-day-old dark-grown seedlings were observed (Fig. 1A). It has been reported that an open hook phenotype appears in 3- and 4-day-old *wag2* single mutants, but not in 2-day-old seedlings (Willige et al., 2012). Therefore, it is possible that the PID family is involved in a negative regulation of hook opening. On the other hand, the hook appeared to open even in the *pid* quadruple mutant when the dark-grown seedlings were incubated under overhead white light (Fig. 1A). The result indicates that the PID family is not necessary for light-inducible hook opening responses.

During continuous-light-induced phototropism, it is proposed for the establishment of the auxin gradient that phot-mediated transcriptional downregulation of the *PID* gene is an important mechanism for producing the asymmetrical localization of PIN3 (Ding et al., 2011). To support the proposed model, the *pid* triple mutant showed defects of continuous-light-induced phototropism (Ding et al., 2011). However, the *pid* quadruple mutant exhibited attenuation of growth rate causing partial impairment of phototropic curvature rates in the continuous-light-induced phototropism (Fig. 1). Furthermore, pulse-induced phototropism was not impaired in the *pid* quadruple mutant when the seedlings were not pretreated with red light (Fig. 2). Therefore, we concluded that the PID family is not critical components for phot-mediated phototropic responses. That is, the proposed model for establishing auxin asymmetry by transcriptional downregulation of *PID* is unlikely a main pathway, and another regulatory mechanism seems to be involved in the production of the auxin gradient during continuous-light-induced phototropism. Recently, Willige et al. (2013) reported that D6 PROTEIN KINASE (D6PK) participates in the phototropism of Arabidopsis hypocotyls. The D6PK family belongs to the AGC kinase family and phosphorylates PIN proteins to regulate auxin transport activity (Zourelidou et al., 2009). Furthermore, continuous-light-induced phototropism was severely impaired in the *d6pk* multiple mutant (Willige et al., 2013), indicating that the D6PK family is required to establish the auxin gradient through regulation.
of PIN activity. Precise physiological analysis will be necessary to clarify the functional roles of the D6PK family in phototropic responses in the near future.

MATERIALS AND METHODS

Plant Materials and Growth Conditions

Arabidopsis (*Arabidopsis thaliana*) seeds of *pid-14* (Salk_049736), *wag1* (Salk_002056C), *wag2* (Salk_070240), and *pid2* (Sail_269_G07) mutants [Columbia (Col) background] were obtained from the Arabidopsis Biological Resource Center. The *pid* quadruple mutant was produced by crossing the above mutants and genotyped using the primer sets listed in Supplemental Table 1. Because the *pid* null mutant was completely sterile (Bennett et al., 1995), *PID/pid* heterozygous *wag1 wag2 pid2* homozygous seedlings were prepared. Seedlings lacking cotyledons were selected for analysis because all of the mutant seedlings showing such phenotypes were the *pid wag1 wag2 pid2* quadruple mutant, although we confirmed the genotypes of the *pid* homozygous plants after the experiments. *35S::PID* and *PID::PID-VENUS* transgenic plants were obtained from Dr. Remko Offringa (Benjamins et al., 2001) and Dr. Marcus Heisler (Michniewicz et al., 2007), respectively. For cloning of *PIN3::PIN3-YFP* and *PIN7::PIN7-YFP*, the inserts were amplified by PCR (Supplemental Table 2) and cloned as follows. The 5′ region of *PIN3* genomic DNA (from −2.0 kb to +0.7 kb from the start of transcription) and the 5′ region of *PIN7* genomic DNA (from −2.1 kb to +0.8 kb from the start of transcription) were cloned in pDONR221P1-P4 (Life Technologies). The 3′ region of *PIN3* genomic DNA (from +0.7 kb to the 3′ untranslated region) and the 3′ region of *PIN7* genomic DNA (from +0.8 kb to the 3′ untranslated region) were cloned in pDONR221P3-P2 (Life Technologies). The *VENUS* cDNAs were cloned in pDONR221P4r-P3r (Life Technologies). The three different pDONR constructs were recombined with pDEST17 by Multi-Gateway LR reaction (Life Technologies) to obtain *PIN3::PIN3-VENUS* and *PIN7::PIN7-VENUS*. These fusion genes were subcloned into pDONR/ZEO by BP reaction (Life Technologies) and then subcloned into binary vector pMDC99 by LR reaction. pMDC99 was obtained...
from the Arabidopsis Biological Resource Center. By Agrobacterium tumefaciens-mediated transformation (Clough and Bent, 1998), PIN3::PIN3-VENUS and PIN7::PIN7-VENUS constructs were transformed into pin3-4 and pin7 (Salk_044687) mutants, respectively. All mutant and transgenic plants were from a Col background.

Etiolated Arabidopsis seedlings were prepared as described previously (Haga and Sakai, 2012). Briefly, seeds of Arabidopsis were sown in 0.2 mL plastic tubes filled with 1.5% agar medium (Sakai et al., 2000), placed in a black plastic box, and kept at 4°C for 3–5 days. Following the induction of germination, the prepared seeds were incubated for 2 days under complete darkness. Seedlings were selected by hypocotyl length (3–5 mm) and kept in the black plastic box during the experiments to maintain high humidity until required for treatments. Experimental manipulations were carried out under dim green light.

**Induction of Phototropism**

For phototropic stimulation, selected seedlings were irradiated using a blue-light-emitting diode light source (470 ± 30 nm, LED-B; Eyela, Tokyo) through two layers of a blue filter (no. 72 film; Tokyo Butai Shomei, Tokyo). The fluence rate was controlled with neutral-density plastic filters (Fujifilm) and by changing the distance from the light source to the seedlings. The direction of phototropic stimulation was perpendicular to the plane of the hook (Haga and Sakai, 2012). For pretreatment with red light, the seedlings were irradiated with overhead red light (660 ± 20 nm, LED-R; Eyela) at 20 μmol m⁻² s⁻¹ for 2 min.

**Measurement of Curvature and Growth**

Images of dark-grown seedlings were recorded just before phototropic stimulation and at 3 h after the onset of stimulation with a digital camera (D5000; Nikon), from which an ultraviolet/infrared light cut filter was removed (ICAS Enterprises IDAS Division, Japan), under infrared illumination (IRDR-110; Nissen Electronics). For time course experiments, images of the seedlings were captured at 10 min intervals using the same equipment. The angles and lengths of the hypocotyls were measured with an e-Ruler (Haga and Sakai, 2012).
Chemical Treatment

BFA was purchased from Nacalai-Tesque, and a fluorescent auxin analog, NBD-NAA, was prepared as described previously (Hayashi et al., 2014). Both chemicals were dissolved with dimethyl sulfoxide. Two hours after red light treatment, the dark-grown pin7 transgenic plants harboring PIN7::PIN7-VENUS were incubated in the growth medium containing BFA at 200 μM for 15 min. For the fluorescent auxin analog, dark-grown wild type and the pid quadruple mutant were incubated in the growth medium containing NBD-NAA at 5 μM for 15 min.

Laser Scanning Confocal Microscopy

Fluorescent signals were detected with a Leica TCS-SP5 confocal laser scanning microscope (Leica Microsystems). VENUS signals were excited with an argon laser at 514 nm, and the spectral detector was set at 525–560 nm. The fluorescent signals derived from NBD-NAA were excited at 488 nm, and the spectral detector was set at 500–530 nm. Green fluorescent protein signals were detected as described previously (Haga and Sakai, 2012). All scans were carried out at a 2,048 × 2,048 pixel resolution with repeated scanning of two lines.

Supplemental Data

The following materials are available in the online version of this article.

Supplemental Figure S1. Effects of blue light irradiation on localization of PHOT1 proteins.

Supplemental Table S1. Gene-specific primers used for genotyping.

Supplemental Table S2. Primers used for cloning of PIN3::PIN3-YFP and PIN7::PIN7-YFP.

ACKNOWLEDGMENTS

We thank the Arabidopsis Biological Resource Center for providing the pid-14 (Salk_049736), wag1 (Salk_002056C), wag2 (Salk_070240), and pid2 (Sail_269_G07) mutants, and the pMDC99 vector. We also thank Professor R.
Offringa (Leiden University), Professor M. Heisler (European Molecular Biology Laboratory), and Dr. A. Miyawaki (RIKEN Brain Science Institute) for providing the 35S::PID seeds, PID::PID-VENUS seeds, and VENUS cDNA, respectively.

Figure 1. Continuous-light-induced second positive hypocotyl phototropism. A, Phenotypes of the pid-14 (Salk_049736) wag1 (Salk_002056C) wag2 (Salk_070240) pid2 (Sail_269_G07) quadruple (quad) mutant. Two-day-old dark-grown seedlings of Columbia (Col) (left panel) and the quad mutant (right panel) are shown. The magnified images are also shown. The seedlings were incubated under continuous white light at 30 µmol m⁻² s⁻¹ for 18 h (each right panel). The quad mutant lacked cotyledons. Black bar, 2 mm. B and C, Hypocotyl phototropism in Col and the quad mutant. Two-day-old dark-grown seedlings were pretreated with (closed circles) or without (open circles) overhead red light (RL). After 2 h, the hypocotyls were stimulated with unilateral blue light at 0.0017 µmol m⁻² s⁻¹ (B) or 0.17 µmol m⁻² s⁻¹ (C) for 6 h. The hypocotyl curvatures were determined at 10 min intervals. The data shown are the means ± SE from eight seedlings. D, Elongation growth of hypocotyls. Hypocotyl lengths of 2-day-old dark-grown Col and quad seedlings were monitored for 8 h at 30 min intervals. The data shown are the means ± SE from eight seedlings.

Figure 2. Pulse-induced first positive hypocotyl phototropism in the pid quadruple (quad) mutant. A, Experimental scheme for pulse-induced phototropism. Two-day-old dark-grown seedlings were pretreated with or without overhead red light (RL). After 2 h, the hypocotyls were stimulated with unilateral blue light (BL) for 60 s. The hypocotyl curvatures were determined 3 h after the onset of BL. B, Effects of RL pretreatment. The dark-grown seedlings were stimulated with unilateral BL at 0.0017 µmol m⁻² s⁻¹ (left side) or 0.17 µmol m⁻² s⁻¹ (right side) for 60 s. The hypocotyl curvatures were determined 3 h after the onset of BL. The data shown are the means ± SE from 11 to 16 seedlings. The asterisk shows a statistically significant difference between the wild type and quad mutant (Student’s t test, \( P < 0.001 \)). C, Fluence-response curves of pulse-induced phototropism. Hypocotyls were stimulated with unilateral BL at various fluences with (closed symbols) or without (gray symbols) RL pretreatment. The data shown are the means ± SE from 16 seedlings. The fitted curves obtained from
Columbia (Col) data (Haga and Sakai, 2012) were reproduced as dotted lines for comparison.

**Figure 3.** Fluence-response relationship of time-dependent second positive phototropism in the *pid* quadruple (quad) mutant. A, Experimental scheme for time-dependent phototropism. Dark-grown seedlings were pretreated with or without red light (RL) and the hypocotyls were irradiated with unilateral blue light (BL) at fixed fluence rates for 3–27 min. Phototropic curvatures were determined 3 h after the onset of BL. B, Time-dependent phototropism without RL pretreatment. The hypocotyls were irradiated with unilateral BL at fixed fluence rates (open symbols, 0.0017 μmol m$^{-2}$ s$^{-1}$; gray symbols, 0.017 μmol m$^{-2}$ s$^{-1}$; and closed symbols, 0.17 μmol m$^{-2}$ s$^{-1}$) for 3 (circles), 9 (triangles), and 27 (squares) min. Black-edged symbols show data obtained from Columbia (Col) seedlings and red-edged symbols show data obtained from the quad mutant. The data shown are the means ± SE from 11 to 16 seedlings. The solid lines represent the fitted curves obtained from Fig. 2B. C, Effects of RL pretreatment on time-dependent phototropism. Other details are as described above.

**Figure 4.** Effects of constitutive expression of *PID* on hypocotyl phototropism. Dark-grown transgenic plants harboring the cauliflower mosaic virus 35S promoter driven *PID* gene (*35S::PID*) were pretreated with or without red light (RL) and the hypocotyls were stimulated with unilateral blue light (BL). A, Hypocotyl phototropism of the transgenic plant. For pulse-induced phototropism with or without RL pretreatment, hypocotyls were stimulated with BL at optimal fluence (see Fig. 2). For time-dependent phototropism, hypocotyls were stimulated with BL at 0.17 μmol m$^{-2}$ s$^{-1}$ for 27 min. For phototropism induced by continuous irradiation, seedlings were irradiated with BL at 0.17 μmol m$^{-2}$ s$^{-1}$ for 3 h. Phototropic curvatures were determined 3 h after the onset of stimulation. The data shown as relative values to the wild type (WT) are the means ± SE from 15 to 16 seedlings. B, Time course of continuous-light-induced phototropism. Dark-grown transgenic plants were pretreated with (closed circles) or without (open circles) RL and the hypocotyls were stimulated with unilateral BL at 0.17
μmol m⁻² s⁻¹ for 6 h. The hypocotyl curvatures were determined at 10 min intervals. The data shown are the means ± SE from eight seedlings. The phototropic responses of Columbia (Col) seedlings obtained from Fig. 1C are reproduced as dotted lines for comparison.

**Figure 5.** Effects of red light (RL) treatment on changes in levels of PID proteins. Dark-grown transgenic plants harboring **PID::PID-VENUS** (Michniewicz et al., 2007) were pretreated with or without RL. After 2 h, VENUS signals were observed around the apical shoots. A, Representative pictures of the apical part in the transgenic plants. Black bar, 200 μm. B, Magnified images of the apical region as shown in Fig. 5A with an orange square and the basal region with a black square. C, Quantification of fluorescent signals in the transgenic plants. The VENUS signals were measured at the apical and basal parts with or without RL pretreatment. The data shown as relative values to averaged data obtained from seedlings without RL pretreatment are the means ± SE from seven to eight seedlings. The asterisk shows a statistically significant difference (Student’s t test, *: P < 0.001).

**Figure 6.** Effects of red light (RL) treatment on PIN proteins. Dark-grown transgenic pin3 mutant harboring **PIN3::PIN3-VENUS** and the pin7 mutant harboring **PIN7::PIN7-VENUS** were pretreated with or without RL. The fluorescent signals were analyzed in the apical shoot regions similar to Fig. 5. A, Quantification of fluorescent signals in the transgenic plants. The VENUS signals were measured at the apical parts 2 h after RL treatment. The data shown as relative values to averaged data obtained from seedlings without RL pretreatment are the means ± SE from 10 to 11 seedlings. The asterisk shows a statistically significant difference (Student’s t test, *: P < 0.05, **: P < 0.01). B, Effects of RL treatment on the distribution of fluorescent signals in the transgenic plants. Representative pictures of the apical part in the transgenic plants are shown. White bar, 50 μm. C, Effects of RL treatment on formation of the brefeldin A (BFA) compartment. After 2 h of RL treatment, the pin7 transgenic plants were
incubated into the growth medium containing BFA at 250 μM for 15 min. White arrowheads indicate BFA compartments. White bar, 25 μm.

**Figure 7.** Effects of red light (RL) treatment on the distribution of auxin during pulse-induced phototropism in the *pid* quadruple (quad) mutant using a fluorescent auxin analog. Dark-grown seedlings pretreated with or without RL were irradiated with a pulse of blue light (BL). After 2.5 h, the seedlings were incubated into growth medium containing a fluorescent auxin analog [7-nitro-2,1,3-benzoxadiazole (NBD)-conjugated naphthalene-1-acetic acid (NAA), NBD-NAA] (Hayashi et al., 2014) at 5 μM for 15 min. The fluorescent signals derived from NBD-NAA were then quantified. A, Representative confocal micrographs during pulse-induced hypocotyl phototropism. Seedlings were stimulated with or without a pulse of BL from the left side at the optimum total fluence (see Fig. 2). The images were obtained around 3 h after stimulation. White bar, 100 μm. B, Distribution of fluorescence derived from NBD-NAA between the irradiated and shaded sides of the hypocotyls during pulse-induced phototropism. The distribution was calculated as the percentage of the signal intensity obtained from the two sides. The data shown are the means ± SE from nine seedlings. C, Representative confocal micrographs during the enhanced pulse-induced phototropism by RL pretreatment. Seedlings pretreated with RL were stimulated with or without a pulse of BL from the left side at the optimum total fluence (see Fig. 2). Other details are described above. D, Distribution of fluorescence derived from NBD-NAA between the irradiated and shaded sides of the hypocotyls during the enhanced pulse-induced phototropism. The data shown are the means ± SE from nine seedlings.

**Figure 8.** Cellular events underlying phytochrome-mediated phototropic enhancement in the apical regions of the shoots. Under dark conditions (upper panel), phytochromes localize at the cytosol. Therefore, transcriptional upregulation of the PIN family does not appear, resulting in a relatively lower abundance of membrane-localized PIN proteins. When irradiated with red light (RL; lower panel), activated phytochromes, i.e., pfr forms, move to the nuclear
membrane and promote transcript levels of the PIN family, resulting in increases in PIN proteins at the plasma membrane. Furthermore, the expression levels of the PID family are reduced by RL treatment. Under such conditions, it is expected that a population of nonphosphorylated PIN proteins is increased at the plasma membrane through a GNOM-sensitive (GNOM₆) pathway rather than a GNOM-resistant (GNOM₃) pathway. On the other hand, it is expected that ROOT PHOTOTROPISM 2 (RPT2) is the most likely candidate involved in phytochrome-mediated regulation of phototropic sensitivity because the rpt2 mutant can respond to only limited ranges of light fluence rates and the transcriptional levels are upregulated by light treatment including RL (Sakai et al., 2000). The present model proposes molecular events just before phototropic stimulation because the present study focused on the molecular mechanisms involved in phototropic enhancement by red light pretreatment. Blue elliptical shapes indicate PIN proteins and red circles show PID proteins. Open red circles indicate phosphorylation of PIN proteins.
Figure 1. Continuous-light-induced second positive hypocotyl phototropism. A, Phenotypes of the *pid-14* (Salk_049736) *wag1* (Salk_002056C) *wag2* (Salk_070240) *pid2* (Sail_269_G07) quadruple (quad) mutant. Two-day-old dark-grown seedlings of Columbia (Col) (left panel) and the quad mutant (right panel) are shown. The magnified images are also shown. The seedlings were incubated under continuous white light at 30 $\mu$mol m$^{-2}$ s$^{-1}$ for 18 h (each right panel). The quad mutant lacked cotyledons. Black bar, 2 mm. B and C, Hypocotyl phototropism in Col and the quad mutant. Two-day-old dark-grown seedlings were pretreated with (closed circles) or without (open circles) overhead red light (RL). After 2 h, the hypocotyls were stimulated with unilateral blue light at 0.0017 $\mu$mol m$^{-2}$ s$^{-1}$ (B) or 0.17 $\mu$mol m$^{-2}$ s$^{-1}$ (C) for 6 h. The hypocotyl curvatures were determined at 10 min intervals. The data shown are the means ± SE from eight seedlings. D, Elongation growth of hypocotyls. Hypocotyl lengths of 2-day-old dark-grown Col and quad seedlings were monitored for 8 h at 30 min intervals. The data shown are the means ± SE from eight seedlings.
Figure 2. Pulse-induced first positive hypocotyl phototropism in the pid quadruple (quad) mutant. A, Experimental scheme for pulse-induced phototropism. Two-day-old dark-grown seedlings were pretreated with or without overhead red light (RL). After 2 h, the hypocotyls were stimulated with unilateral blue light (BL) for 60 s. The hypocotyl curvatures were determined 3 h after the onset of BL. B, Effects of RL pretreatment. The dark-grown seedlings were stimulated with unilateral BL at 0.0017 μmol m$^{-2}$ s$^{-1}$ (left side) or 0.017 μmol m$^{-2}$ s$^{-1}$ (right side) for 60 s. The hypocotyl curvatures were determined 3 h after the onset of BL. The data shown are the means ± SE from 11 to 16 seedlings.
